many hypertensives have benefited year after year

cardiovascular benefits

cardiac output usually maintained

sodium and fluid retention generally controlled

two highly effective complementary agents

As a fixed combination, ALDORIL is not indicated for initial therapy since hypertension requires therapy titrated to the individual patient. If an available strength of ALDORIL meets the patient's titrated needs, the combination drug may be more convenient in patient management. Therapy should be reevaluated as necessary.

ALDORIL is contraindicated in active hepatic disease; anuria; hypersensitivity to methyldopa or to hydrochlorothiazide or other sulfonamide-derived drugs; if previous methyldopa therapy has been associated with liver disorders. In patients with renal disease, thiazides may precipitate azotemia. Use with caution in patients with severe renal disease or impaired hepatic function.

It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. For more details, see the brief summary of prescribing information.

For a brief summary of prescribing information, please see following page.

practical benefits

- **effects on daily activities usually minimal:** There is less frequent symptomatic postural hypotension with ALDORIL than with many other antihypertensive agents. Exercise hypotension and diurnal blood pressure variations rarely occur.
- **greater dosage convenience:** a b.i.d. regimen is possible for many patients
- **four dosage strengths:** offer the widest range of dosage strengths available in a combination antihypertensive

TABLETS
ALDORIL®-25 containing 250 mg ALDOMET® (Methyldopa, MSD) and 25 mg HydroDIURIL® (Hydrochlorothiazide, MSD)

TABLETS
ALDORIL®-15 containing 250 mg ALDOMET® (Methyldopa, MSD) and 15 mg HydroDIURIL® (Hydrochlorothiazide, MSD)

TABLETS
ALDORIL® D50 containing 500 mg ALDOMET® (Methyldopa, MSD) and 50 mg HydroDIURIL® (Hydrochlorothiazide, MSD)

TABLETS
ALDORIL® D30 containing 500 mg ALDOMET® (Methyldopa, MSD) and 30 mg HydroDIURIL® (Hydrochlorothiazide, MSD)

MSD

Antihypertensive TABLETS
ALDORIL®-15
methyldopa 250 mg and hydrochlorothiazide 15 mg

WARNING

This fixed combination drug is not indicated for initial therapy of hypertension. Hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see **Warnings**); anuria; hypersensitivity to methyldopa or to hydrochlorothiazide or other sulfonamide-derived drugs.

Warnings: METHYLDOPA—**It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions.**

With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood.

At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

P24,124

Fever has occurred within the first three weeks of therapy, sometimes with eosinophilia or abnormalities in one or more liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually within the first two to three months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever, abnormalities in liver function tests, or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients.

Rarely, reversible reduction of white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Follow patients carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

HYDROCHLOROTHIAZIDE—Use with caution in severe renal disease. In patients with renal disease, thiazides may precipitate azotemia. Cumulative effects may develop in patients with impaired renal function. Use with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma. May add to or potentiate action of other antihypertensive drugs. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possibility of exacerbation or activation of systemic lupus erythematosus has been reported. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity; read circulars for lithium preparations before use of such concomitant therapy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant requires that anticipated benefits be weighed against possible risks.

Methyldopa and thiazides cross the placental barrier and appear in cord blood.

No unusual adverse reactions have been reported in association with the use of methyldopa during pregnancy. Although no obvious teratogenic effects have been reported, the possibility of fetal injury cannot be excluded.

The hazards of thiazides crossing the placental barrier include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in adults. Methyldopa and thiazides appear in breast milk. Patients taking ALDORIL should not nurse.

Precautions: METHYLDOPA—Should be used with caution in patients with history of previous liver disease or dysfunction (see **Warnings**). May interfere with measurement of urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites. Involuntary choreoathetotic movements have been observed in patients with severe bilateral cerebrovascular disease. If such movements occur, stop the drug. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

HYDROCHLOROTHIAZIDE—Perform periodic determination of serum electrolytes to detect possible electrolyte imbalance. Observe all patients for evidence of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when patient is vomiting excessively or receiving parenteral fluids. Warning signs or symptoms of fluid and electrolyte imbalance include dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting. Hypokalemia may develop, especially with brisk diuresis, in severe cirrhosis, with concomitant corticosteroids or ACTH, after prolonged therapy, or with inadequate oral electrolyte intake. Hypokalemia can sensitize or exaggerate response of heart to toxic effects of digitalis (e.g., increased ventricular irritability). Hypokalemia may be avoided or treated by use of potassium supplements, such as foods with a high potassium content. Although any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease), chloride replacement may be required in metabolic alkalosis. Dilutional hyponatremia may occur in edematous patients in hot weather; appropriate therapy is water restriction, rather than administration of salt, except in rare instances when the hyponatremia is life threatening. In actual salt depletion, appropriate replacement is the therapy of choice.

Hyperuricemia may occur or acute gout may be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged; latent diabetes mellitus may become manifest. Thiazides may increase responsiveness to tubocurarine. Antihypertensive effects of the drug may be enhanced in postsympathectomy patients. May decrease arterial responsiveness to norepinephrine; this diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. If progressive renal impairment becomes evident, consider withholding or discontinuing diuretic therapy. Thiazides may decrease serum PBI levels without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Pathological changes in the parathyroid glands with hypercalcemia and hypophosphatemia have been observed in a few patients on prolonged therapy; thiazides should be discontinued before testing for parathyroid function.

Adverse Reactions: METHYLDOPA—*Central nervous system:* Sedation, headache, asthenia or weakness; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression. *Cardiovascular:* Bradycardia, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.) *Gastrointestinal:* Nausea, vomiting, distention, constipation, flatus, diarrhea, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis. *Hepatic:* Abnormal liver function tests, jaundice, liver disorders. *Hematologic:* Positive Coombs test, hemolytic anemia. Leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells and rheumatoid factor. *Allergic:* Drug-related fever, lupus-like syndrome, myocarditis. *Other:* Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, impotence, decreased libido, dermatologic reactions including eczema and lichenoid eruptions, mild arthralgia, myalgia.

HYDROCHLOROTHIAZIDE—*Gastrointestinal system:* Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis, sialadenitis. *Central nervous system:* Dizziness, vertigo, paresthesias, headache, xanthopsia. *Hematologic:* Leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia, hemolytic anemia. *Cardiovascular:* Orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics). *Hypersensitivity:* Purpura, photosensitivity rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), fever, respiratory distress including pneumonitis, anaphylactic reactions. *Other:* Hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, transient blurred vision. Whenever adverse reactions are moderate or severe, thiazide dosage should be reduced or therapy withdrawn.

Note: Tolerance may occur, usually between the second and third month of therapy. Increasing dosage of either component separately or together frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

How Supplied: Tablets ALDORIL®-15, containing 250 mg methyldopa and 15 mg hydrochlorothiazide, bottles of 100 and 1000; Tablets ALDORIL®-25, containing 250 mg methyldopa and 25 mg hydrochlorothiazide, bottles of 100 and 1000; Tablets ALDORIL® D30, containing 500 mg methyldopa and 30 mg hydrochlorothiazide, bottles of 100; Tablets ALDORIL® D50, containing 500 mg methyldopa and 50 mg hydrochlorothiazide, bottles of 100.

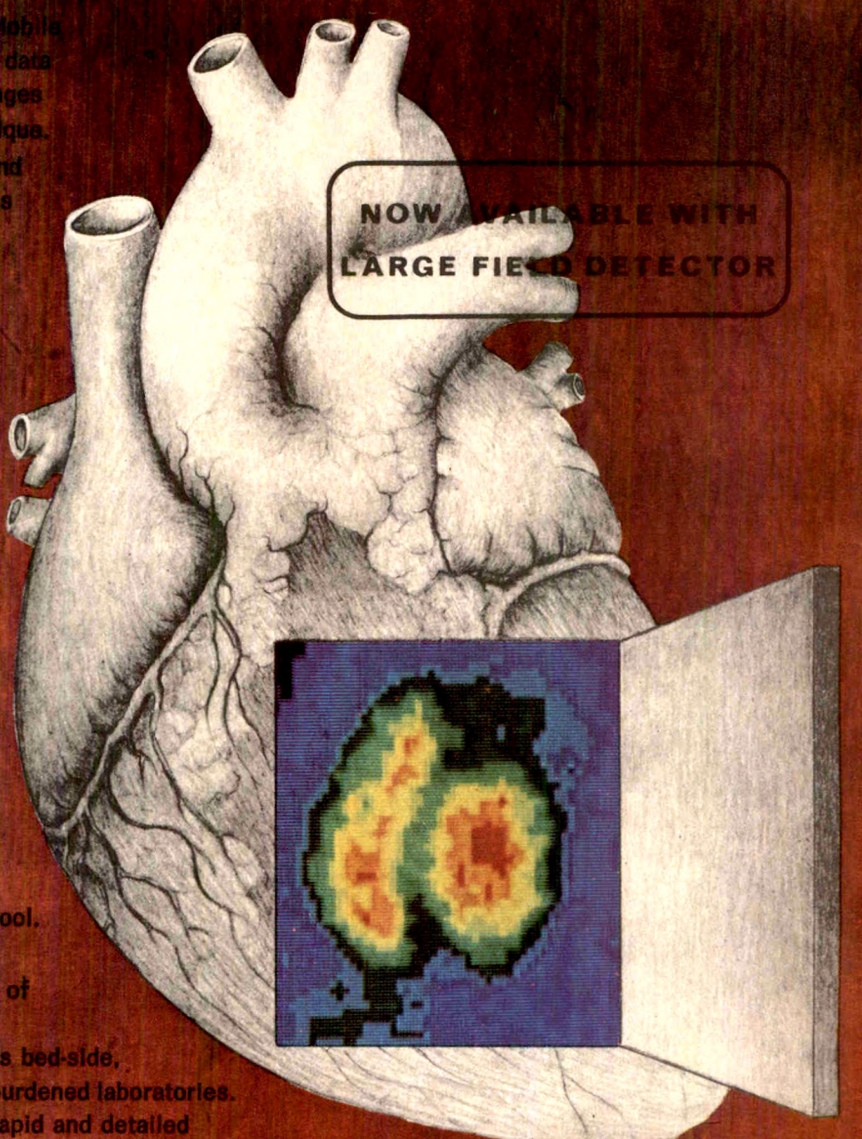
For Non-Invasive Dynamic Heart Studies

DYMAX-MB

A COMPUTERIZED MOBILE GAMMA CAMERA

Provides the Technique For Today – and Tomorrow

Results obtained using the DYMAX-MB Mobile Camera with its powerful minicomputer data processor, clearly demonstrate the advantages of radiocardiology as a diagnostic technique. DYMAX-MB is compact, fully mobile and simple to operate. The camera produces studies with excellent resolution and uniformity at both low and high countrates, while the self-contained processor provides instant clinical analysis of the data. Among the heart functions which can be studied "live" are wall motion, ejection fraction, cardiac output, interventricular shunts and other parameters of major importance.



Analytical procedures are speeded by automatic repeat of previously established protocols. On-the-spot analysis enables the attending physician to immediately evaluate results, eliminating the delays of batch processing at a central installation, thus maximising the efficacy of the DYMAX-MB.

Check for yourself the significant advantages of this highly efficient clinical tool.

You can :

- Spare your patient the trauma of catheterization.
- Complete the diagnosis at the patient's bed-side, sparing him exhausting movement to overburdened laboratories.
- Receive pre-processed data for more rapid and detailed interpretation than was possible with earlier techniques.

Until you examine the performance of this outstanding unit, you haven't heard the last word. Call us or write for more information or demonstration.

In Edema* or Hypertension*

Potassium-Sparing

DYAZIDE®

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

Makes Sense

Serum K^+ and BUN should be checked periodically (See Warnings).

Before prescribing, see complete prescribing information in SK&F Co. literature or *PDR*. A brief summary follows:

* **WARNING**
This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Watch for signs of impending coma in severe liver disease. If spironolactone is used concomitantly, determine serum K^+ frequently; both can cause K^+ retention and elevated serum K^+. Two deaths have been reported with such concomitant therapy (in one, recommended dosage was exceeded, in the other serum electrolytes were not properly monitored). Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia have been reported with thiazides. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effect may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances. Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and, rarely, allergic pneumonitis have occurred with thiazides alone.

Supplied: Bottles of 100 and 1000 capsules; Single Unit Packages of 100 (intended for institutional use only).

For patients who need K^+Cl^- one sparkles bright:

KLORVESS® EFFERVESCENT GRANULES offer SPARKLING FAST DISSOLUTION

Each packet (2.8 g) provides 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, and L-lysine monohydrochloride 0.913 g.

- **ready in *seconds* instead of minutes —fast dissolution so unique it's patented***
- **pleasant citrus flavor**
- **each packet delivers 20 mEq of potassium and chloride**
- **easily carried in patient's pocket or purse**
- **can be mixed with water or other liquid for pleasant daily dosage**
- **sugar, sodium, carbohydrate and dye free**

Give your patients the KLORVESS sparkle

Give your patients the KLORVESS® sparkle

Klorvess® Effervescent Granules and Klorvess® (potassium chloride) 10% Liquid

Brief summary of prescribing information

DESCRIPTION: *Klorvess Effervescent Granules:* Each packet (2.8 g) contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g in a sodium-, sugar- and carbohydrate-free effervescent formulation. Dissolution of the packet contents in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

Klorvess (potassium chloride) 10% Liquid: Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

INDICATIONS: For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

CONTRAINDICATIONS: Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

PRECAUTIONS: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements. Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis. High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest. To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve the packet contents of *Klorvess Effervescent Granules* in 3 to 4 ounces of cold water, fruit juice or other liquid or dilute each tablespoonful of *Klorvess (potassium chloride) 10% Liquid* in 3 to 4 ounces of cold water. Both of these solutions should be ingested slowly with or immediately after meals.

ADVERSE REACTIONS: Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest. The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

DOSAGE AND ADMINISTRATION: *Klorvess Effervescent Granules:* Adults—One packet completely dissolved 2 to 4 times daily depending upon the requirements of the patient.

Klorvess (potassium chloride) 10% Liquid: Adults—One tablespoonful (15 ml) completely diluted in cold water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating.

OVERDOSAGE: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

HOW SUPPLIED: *Klorvess Effervescent Granules*—packages of 30 packets (2.8 g each). *Klorvess (potassium chloride) 10% Liquid* (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Effervescent Granules and Liquid are also available in institutional packaging as follows: *Klorvess Effervescent Granules*—packages of 1000 packets; *Klorvess Liquid*—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

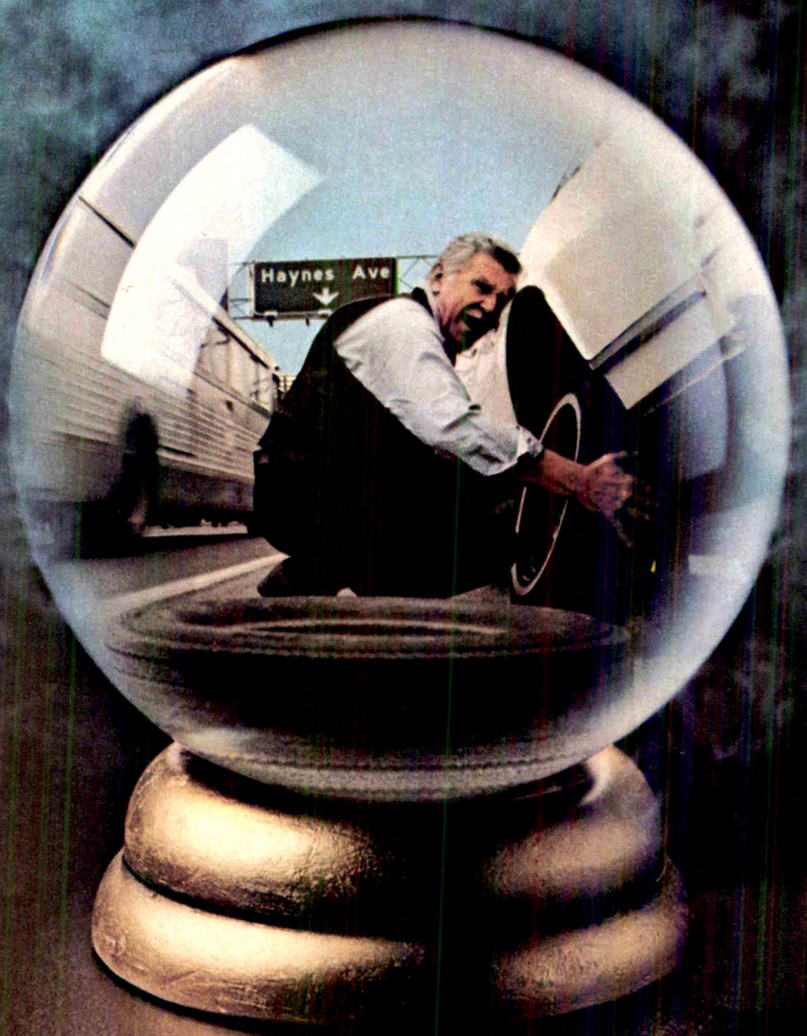
Predictable angina*



...during episodes of emotional stress or physical exertion

SUMMARY OF PRESCRIBING INFORMATION

* **Indications:** Based on a review of this drug by The National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: The chewable dosage form of SORBITRATE is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety.

Precautions: Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: *Individual Dose:* To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an angina attack. CHEWABLE SORBITRATE® (isosorbide dinitrate) may be taken for prompt relief of angina pain three or four times daily. Although the onset and duration of effect of coronary nitrates may vary, following is the generally reported range of these values for CHEWABLE SORBITRATE.

Onset of Effect: Two to five minutes.
Duration of Effect: One to two hours.

Up to 2 hours of angina protection. At mealtime and any other time of stress.

CHEWABLE SORBITRATE®

(ISOSORBIDE DINITRATE) 5mg. and 10mg.

CLINICAL STUDIES

1 **Arrhythmia in Hypertrophic Cardiomyopathy: Exercise Electrocardiographic and 48 Hour Ambulatory Assessment With and Without Beta Adrenergic Blocking Therapy**

WILLIAM J. McKENNA, SIVABAKIYAM CHETTY, CELIA M. OAKLEY and JOHN F. GOODWIN

Submaximal treadmill exercise electrocardiography and 48 hour ambulatory electrocardiographic monitoring in 30 patients with hypertrophic cardiomyopathy revealed that asymptomatic ventricular arrhythmias commonly occur in such patients and their frequency is not reduced by beta adrenergic blocking therapy. During exercise testing ventricular extrasystoles developed in 60 percent of the patients and paired ventricular extrasystoles in 10 percent. This frequency was almost identical with and without beta adrenergic blocking therapy. These results indicate the need for alternative antiarrhythmic agents for the treatment of ventricular arrhythmias in patients with this disorder. Currently available beta blocking drugs should principally be used for the control of established and paroxysmal atrial fibrillation and to alleviate symptoms, especially angina pectoris.

6 **M Mode Echocardiography in Hypertrophic Cardiomyopathy: Diagnostic Criteria and Prediction of Obstruction**

YOSHINORI L. DOI, WILLIAM J. McKENNA, JÜRGEN GEHRKE, CELIA M. OAKLEY and JOHN F. GOODWIN

M mode echocardiographic studies of 70 patients with clinical and angiographic evidence of hypertrophic cardiomyopathy revealed that ventricular septal thickness of 13 mm or greater plus systolic anterior movement of the mitral valve or mid systolic closure of the aortic valve best differentiated obstructive (resting and labile) from nonobstructive hypertrophic cardiomyopathy and the heart with obstructive hypertrophic cardiomyopathy from the normal heart. No single echocardiographic feature was present in more than 83 percent of patients and therefore by itself diagnostic of hypertrophic cardiomyopathy.

15 **Left Ventricular Relaxation and Filling Pattern in Different Forms of Left Ventricular Hypertrophy: An Echocardiographic Study**

PETER HANRATH, DETLEF G. MATHEY, RALF SIEGERT and WALTER BLEIFELD

This study of left ventricular relaxation and filling in different forms of left ventricular hypertrophy indicates that patients with hypertrophic obstructive cardiomyopathy and chronic left ventricular pressure overload have an

Continued on page A15

Introducing the Datascope Hospital System.

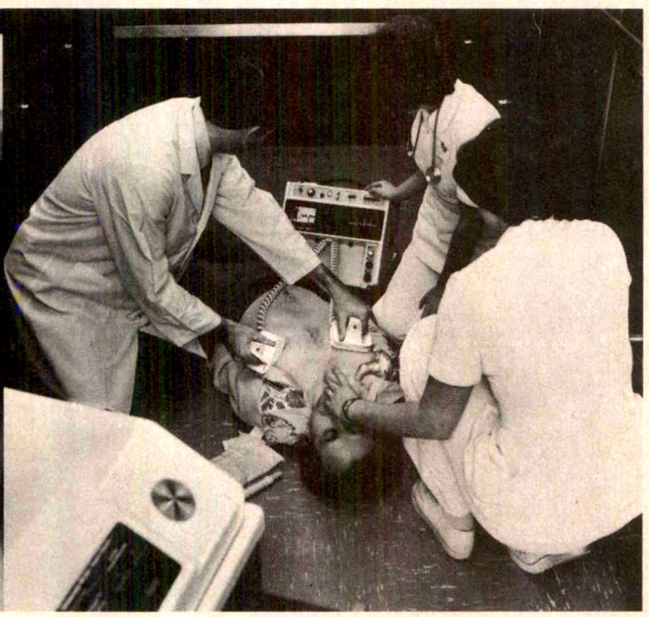
The most advanced defibrillator system ever put on a crash cart. Or ever taken off one.

Defibrillators for the hospital have always been a compromise.

Those designed for a crash cart are difficult to use away from the crash cart because they're so heavy and unwieldy.

And the portables, while offering more portability, don't have the capability of their heavier counterparts.

You've had to choose between performance and portability. Until now, you couldn't have both.



We're pleased to offer you the first defibrillator system that doesn't force you to compromise: the Datascope Hospital System.

The Datascope Hospital System is the M/D3 defibrillator/monitor/recorder and the support module in which it nests.

Since you may need a defibrillator on a cart, or a portable to reach and transport a patient, we designed the M/D3 unlike other defibrillators.

The Datascope Hospital System separates in a manner that makes sense. The defibrillator, monitor and recorder all remain intact as a compact unit. So you always have everything you need with you where you need it, when you need it. The support module separates and remains on the crash cart, leaving unnecessary weight behind.

On or off a crash cart, it has features found in no other system.

The scope on the Hospital System is 5″ in diameter. The same size as scopes on defibrillators weighing 35 to 40 pounds.

The monitor offers 2 large digital displays. One for heart rate and one for delivered energy. (To our mind, lights are simply not an adequate indication of such critical parameters.)

The support module for the Datascope Hospital System has a built-in delivered energy tester. Here again, instead of a light that merely indicates, there's a meter that accurately measures the delivered energy throughout the entire range of the defibrillator.

There's a document switch on the defibrillator paddles to trigger the strip chart recorder. And the paddles rapidly disconnect for easy changes or replacement.

Perhaps the most important innovation of all, ours is the first defibrillator system to end the fear of battery failure.

The M/D3 incorporates three totally independent power systems: complete ac line operation, nickel-cadmium batteries that recharge in less than five hours, and the world's first Lithium Emergency Power Pack. This revolutionary power pack remains fully-charged in the unit for up to 5 years. In the event that all other power sources fail, you merely activate the Emergency Pack to instantly power the monitor and defibrillator.

For all of its features, the M/D3 weighs less than 28 pounds and is extremely easy to operate.

We urge you to see a demonstration of the new Datascope Hospital System. There has never been any defibrillator in a hospital like it. On or off a crash cart.

To arrange for a demonstration call us at 201-265-8800. Datascope Corp., Box 5-AA, Paramus, NJ 07652. In Europe: Datascope B.V., Post Box 26, 3870 CA, Hoevelaken, Holland.

The Datascope M/D3 Hospital System

No matter how close the copy...

wouldn't you rather have the original?

This statuette of Tutankhamun, as the god Horus of Lower Egypt, has been reproduced many times — often in solid gold replicas worth thousands. The original, however, remains priceless.

Lee Boltin/Metropolitan Museum of Art

The original dipyridamole.

During the 17 years that Persantine has been used for long-term therapy of chronic angina pectoris,* physicians have developed an increasing familiarity with this drug. This familiarity is reflected in a steady growth in Persantine use during those years. Clinicians today have extensive experience with dipyridamole, and this experience has been derived from one compound.
Persantine...from Boehringer Ingelheim Ltd.
The original dipyridamole.

Persantine®
(dipyridamole)

*INDICATIONS—Based on a review of this drug by the National Academy of Science-National Research Council and/or other information. FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.

ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg (2 tablets) three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.
Tablets of 25 mg
For complete details, please see the full prescribing information.

Boehringer Ingelheim Ltd.
Ridgefield, CT 06877

abnormally prolonged relaxation period often associated with a reduced increase in diameter during a shortened rapid filling phase. In chronic pressure overload the end-diastolic dimensions are normal because atrial contraction compensates for the reduction in early diastolic filling. In hypertrophic obstructive cardiomyopathy, the compensatory mechanism fails to achieve a normal left ventricular end-diastolic dimension.

24 **The Heterogeneity of Hypertrophic Cardiomyopathy: An Autopsy and One Dimensional Echocardiographic Study**

JEANNE Y. WEI, JAMES L. WEISS and BERNADINE H. BULKLEY

At autopsy only two of nine consecutive patients with a diagnosis of idiopathic hypertrophic subaortic stenosis on one dimensional echocardiography exhibited asymmetric septal hypertrophy and myocardial fiber disarray. The other seven had no evidence of hypertrophic cardiomyopathy on gross examination or light microscopy. Two had concentric left ventricular hypertrophy, one had severe coronary atherosclerosis with cardiac hypertrophy, one had cardiac amyloidosis and three had no evidence of cardiac disease. These data suggest that systolic anterior motion of the mitral valve and asymmetric septal hypertrophy may be sensitive but poorly predictive of idiopathic hypertrophic subaortic stenosis in a general hospital population.

33 **Hypertrophic Cardiomyopathy After Aortic Valve Replacement**

RICHARD THOMPSON, MOHAMMED AHMED, RONALD PRIDIE and MAGDI YACOUB

Although the association of hypertrophic cardiomyopathy and aortic valve stenosis is well documented, this report describes six women who first manifested hypertrophic cardiomyopathy 3 to 5 years after successful homograft replacement of the aortic valve. In these patients left ventricular mass showed no significant regression and actually increased progressively with the passage of time. This increase in mass was accompanied by a similar progressive increase in the ejection fraction and in the septal/posterior wall thickness ratio. Although it seems probable that these six patients represent another facet in the spectrum of hypertrophic cardiomyopathy, the mechanism that allows continuous left ventricular hypertrophy to occur after successful valve replacement in the absence of abnormal loading conditions is not known.

42 **Hemodynamic Evaluation of Patients With Combined Mitral and Aortic Prostheses**

WILLIAM A. BAXLEY and BENIGNO SOTO

Based on a 4 year experience with 22 patients with combined aortic and mitral mechanical valve prostheses who required complete hemodynamic evaluation, this report describes a standardized procedure of transthoracic needle puncture of the left ventricle providing reasonable efficiency and safety. Although there were no fatal or permanent residual sequelae in this study, 18 percent had significant complications attributable to the diagnostic procedure. Alternative methods include retrograde aortic catheterization of the prosthesis, transseptal left atrial catheterization with anterograde crossing of the mitral prosthesis, and transapical pressure measurement with a smaller needle combined with quantitative left atrial angiography.

48 **Coronary Hemodynamic Effects of Ergonovine Maleate in Human Subjects**

ARTHUR E. ORLICK, DONALD R. RICCI, PAUL R. CIPRIANO, DIANA F. GUNTHANER and DONALD C. HARRISON

This study of the coronary hemodynamic effects of ergonovine maleate in 15 patients suggests that this agent effectively limits the ability of the myocardial arteriolar bed to dilate in response to an augmented myocardial

Continued on page A20

Liquid K...
It's no picnic.

The tasteless Slow-K tablet that doesn't insult food

Slow-K®

CIBA 165

(potassium chloride) slow-release tablets 8 mEq

The right taste

The right taste in potassium supplementation is no taste or aftertaste. That's the taste of Slow-K. Tasteless. Even when taken with meals, it allows patients to enjoy the flavor of food. Compare this with liquid K's unpleasant taste. It's easy to see why Slow-K was the overwhelming choice of patients in taste comparisons with liquid KCl and potassium gluconate preparations.[1,2]

The right salt

Potassium chloride, the active ingredient of Slow-K, "...is the salt of choice to correct the hypokalaemic alkalosis resulting from thiazides and related diuretics...."[3]

The right delivery

Slow-K delivers KCl slowly, through controlled, gradual release within the gastrointestinal tract. Patients encounter much less nausea, heartburn and diarrhea than with liquid KCl, as demonstrated by comparative studies.[1] (Occurrence of abdominal cramping was comparable.)

Patients also appreciate the convenience of a small, easy-to-carry Slow-K tablet.

Slow-K...When compliance with liquid K supplements is a problem*

*Slow-release potassium chloride tablets should be reserved for patients who cannot tolerate, refuse to take, or have compliance problems with liquid K preparations because of reports of GI ulceration and bleeding with slow-release KCl tablets (total number of GI lesions in both foreign countries and the United States remains less than one per 100,000 patient-years). The incidence of lesions with enteric-coated KCl tablets is 40-50 per 100,000 patient-years.

Please turn page for prescribing information.

CIBA

Slow-K
(potassium chloride)
slow-release tablets

DESCRIPTION

Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS

BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.

2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.

3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS

In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS

Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS

Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion, particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram, and clinical status of patient.

ADVERSE REACTIONS

Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE

Usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for prevention of hypokalemia to 40-100 mEq per day or more for treatment of potassium depletion.

Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability and insomnia associated with anxiety neuroses and transient situational disturbances; anxiety associated with depressive symptoms and as a treatment of symptoms of anxiety if such symptoms are a significant feature of functional or organic disorders, particularly gastrointestinal or cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatric patients requires caution and frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring of vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for (lorazepam) Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

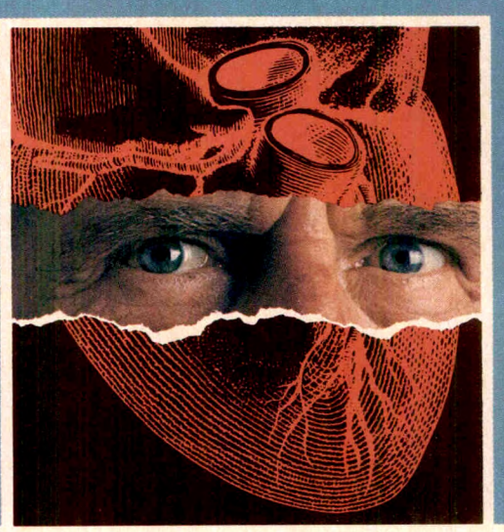
The anxious heart. Since anxiety so often accompanies cardiovascular disease, you may wish to institute adjunctive therapy to help bring this complicating factor under control.

Seven benzodiazepines are now at your disposal. All of them are anxiolytics. One of them—Ativan (lorazepam)—has been specifically evaluated in seven double-blind, controlled studies involving 423 patients (211 on Ativan) and found significantly effective in the relief of anxiety associated with organic and functional cardiovascular disorders. The cardiovascular component has not, of course, been shown to be significantly benefited by such therapy.

In addition to this outstanding record of clinical usefulness, Ativan offers you a unique pharmacokinetic profile. Unlike older benzodiazepines, it does not generate multiple active metabolites; steady-state serum levels are rapidly achieved and disappear rapidly once you decide to discontinue therapy. (The pharmacokinetic profile of a drug can define such characteristics as absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Compatible with cardiotonics, antihypertensives, diuretics, anticoagulants and nonnarcotic analgesics*...usually well tolerated...simple to use on a b.i.d. schedule...a preferred prescription to control anxiety in cardiovascular disease.



*No evidence of any clinically significant interaction between Ativan and any other medication given concomitantly was observed in clinical studies. All benzodiazepines, however, including Ativan, produce added CNS depressant effects when administered with alcohol and other CNS depressants.

See important information on preceding page.

Ativan® (IV)
for (lorazepam)
Anxiety

metabolic demand. There was an unchanged coronary vascular resistance to ergonovine despite augmented myocardial oxygen demand. Such limitation in arteriolar autoregulatory capacity may be important in producing chest pain and myocardial ischemia in patients with significant coronary occlusion who receive ergonovine although their condition does not meet the criteria for variant angina.

EXPERIMENTAL STUDIES

53 Myocardial Prostaglandin E Release by Nitroglycerin and Modification by Indomethacin

ESTEBAN MORCILLIO, PHILIP R. REID, NORMAL DUBIN, RAMESH GHODGAONKAR and BERTRAM PITT

Examining the role of prostaglandin E in mediating the effects of trinitroglycerin on coronary vascular resistance and systemic blood pressure in dogs, these investigators conclude that the mechanism of action of trinitroglycerin may be partially mediated through the prostaglandin system. During the intravenous infusion of trinitroglycerin there was a significant increase in myocardial prostaglandin E production associated with the expected reduction in systemic blood pressure and decrease in coronary vascular resistance. With at least partial inhibition of myocardial prostaglandin E production after indomethacin, there was a significantly lesser reduction in coronary vascular resistance and systemic blood pressure during the second trinitroglycerin infusion.

58 Evidence for a Flow-Independent Contribution to the Phenomenon of Thallium Redistribution

JOSEPH L. GERRY, Jr., LEWIS C. BECKER, JOHN T. FLAHERTY and MYRON L. WEISFELDT

This examination of the relation between thallium distribution and regional myocardial blood flow in dogs after 2 hours of continuous myocardial ischemia suggests a significant component of thallium redistribution may be flow-independent. Pacing in the presence of left circumflex arterial stenosis produced a significant mass of myocardium with a less drastic reduction in blood flow (40 percent) compared with that produced by coronary ligation. In the presence of this milder reduction in flow these data indicate that a considerable degree of thallium redistribution can occur over a 2 hour period even when inequality of flow between the ischemic and nonischemic zone is maintained. However, it is still unclear whether these results are directly applicable to clinical thallium scintigraphic studies during exercise in human subjects.

METHODS

63 Assessment of Right Ventricular Function at Rest and During Exercise in Patients With Coronary Heart Disease: A New Approach Using Equilibrium Radionuclide Angiography

ROBERT SLUTSKY, WAYNE HOOPER, KENNETH GERBER, ALEXANDER BATTLER, VICTOR FROELICHER, WILLIAM ASHBURN and JOEL KARLINER

Equilibrium angiography in this study of 20 normal persons and 50 patients with angiographically documented coronary artery disease proved useful and reliable for evaluating right ventricular function. At rest there was no difference in the right ventricular ejection fraction in both groups. With exercise the ejection fraction increased in the normal subjects and in patients with coronary artery disease and no right coronary stenosis but remained unchanged in those with right coronary stenosis (alone or combined with other lesions). These data demonstrate that during exercise the right ventricle shows dysfunction as a result of local ischemia and altered loading conditions due to left ventricular dysfunction.

72 Complete Abolition of the Reentrant Supraventricular Tachycardia Zone Using a Modality of Cardiac Pacing With Simultaneous Atrioventricular Stimulation

RUEY J. SUNG, JANUARIUSZ L. STYPEREK and AGUSTIN CASTELLANOS

An experimentally designed new pacemaker has been developed that is capable of sensing either an atrial or a ventricular signal and in turn triggers simultaneous atrioventricular (A-V) stimulation. In some patients with re-

Cardiodyne

Announcing the formation of

Berlex Laboratories Inc.

a new pharmaceutical company that will offer the best of two worlds

Dear Doctor:

You are familiar with the product that appears on the opposite page, but you are not familiar with the company name that now appears on that product, Berlex Laboratories Inc.

Berlex Laboratories Inc. is the new American subsidiary of Schering AG, Berlin, West Germany, one of the world's most respected research-oriented pharmaceutical manufacturers, with a history of innovation and excellence dating back to 1851. Schering AG is not connected with Schering-Plough Corporation, Kenilworth, New Jersey.

Berlex Laboratories was formed through the acquisition of certain products and manufacturing and research facilities of Cooper Laboratories, Inc. The more familiar preparations in the specialties of cardiology, internal medicine, allergy and general medicine include:

Aminodur® Dura-Tabs® (aminophylline)
Deconamine® (chlorpheniramine maleate/d-pseudoephedrine hydrochloride)
Elixophyllin® (theophylline)
Elixicon® Suspension (theophylline)
Kay Ciel® (potassium chloride)
Pyocidin-Otic® (polymyxin-hydrocortisone)
Quinaglute® Dura-Tabs® (quinidine gluconate)
Sus-Phrine® (epinephrine)
Therapav® (papaverine hydrochloride)

In the future, Berlex Laboratories plans to augment these well-established products with others not currently available in the United States but which have gained high acceptance by physicians around the world. Berlex Laboratories' parent company manufactures and distributes over 100 ethical products through 120 plants and subsidiaries in 140 countries.

Although you are unfamiliar with our name now, you will soon know us as physicians in other countries know and respect our parent company.

Berlex Laboratories looks forward to serving you with products developed by our worldwide research resources. Products to meet the challenges of tomorrow will come from commitment to research today. Berlex Laboratories Inc. is making that commitment now to meet the challenges of tomorrow.

BERLEX Laboratories Inc.

When the compromised arrhythmic patient needs round-the-clock, year-after-year protection

Quinaglute® DURA-TABS® 324 mg
(quinidine gluconate)®

CONTRAINDICATIONS:
Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.
Partial A-V or complete heart block, or intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening.
Renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defects, ventricular premature beats, ventricular tachycardia or flutter while on the drug.
Marked cardiac enlargement, particularly with congestive failure, poor renal function, and especially renal tubular acidosis.
Idiosyncrasy or hypersensitivity to quinidine.

WARNINGS:
In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate.

PRECAUTIONS:
The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy.
Quinidine in large doses may reduce the contractile force of the heart, therefore, extreme caution should be exercised in using the drug in patients with severe heart disease, hypotension or digitalis intoxication. The potential disadvantages and benefits must be weighed.
It should be administered cautiously, if at all, to senile patients.
Hospitalization for close clinical observation, electrocardiographic monitoring, and possibly plasma quinidine levels is indicated when large doses are used or with patients who present an increased risk.

ADVERSE REACTIONS:
Symptoms of cinchonism, ringing in ears, headache, nausea, disturbed vision may appear in sensitive patients after a single dose of the drug.
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism, hypotension.
Gastrointestinal: Nausea, vomiting, abdominal pain, diarrhea.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision fields, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Cutaneous flushing with intense pruritus.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest.
See package insert for full information.

current A-V nodal reentrant tachycardia, such simultaneous stimulation by the pacemaker resulted in impulse collision in the A-V junction and complete abolition of the zone of reentrant tachycardia. These preliminary results suggest that implantable pacemakers with this new modality may soon be a clinical reality.

PEDIATRIC CARDIOLOGY

79 Comparison of M Mode Echocardiography and Pathologic Findings in the Hypoplastic Left Heart Syndrome

JOHN L. BASS, GIORA BEN-SHACHAR and JESSE E. EDWARDS

Correlation of M mode echocardiograms and pathologic specimens from 18 infants with the hypoplastic left heart syndrome indicates that noninvasive findings are not always sufficient to diagnose this condition, which involves a spectrum of hypoplasia or atresia of the mitral valve, left ventricle and aortic valve. Additional studies may be necessary in some patients. The most reliable echocardiographic finding was an excursion of 5 mm or less of the anterior leaflet of the mitral valve or inability to detect the mitral valve. In every case the pathologic examination revealed a smaller than anticipated left ventricular diameter as determined qualitatively with echocardiography.

87 Hypoplastic Left Heart Syndrome: Experience With Palliative Surgery

WILLIAM I. NORWOOD, JAMES K. KIRKLIN and STEPHEN P. SANDERS

A new effective palliative procedure for hypoplastic left heart syndrome resulted in early ongoing survival of two infants with aortic atresia. In this new multistage surgical approach, a preliminary palliative approach, which includes placement of a valved conduit from the right ventricular free wall to the descending aorta, is followed by physiologic correction of the lesion.

92 Total Anomalous Pulmonary Venous Connection in Infancy: Influence of Age and Type of Lesion

KEVIN TURLEY, WILLIAM Y. TUCKER, DANIEL J. ULLYOT and PAUL A. EBERT

Nineteen of 22 infants who underwent surgical correction of total anomalous pulmonary venous connection in their 1st year of life survived operation, yielding an 87 percent hospital survival rate. The strongest determinants of survival were the type of lesion, pulmonary venous obstruction and depressed left ventricular function, but not age. The timing of corrective surgery should be influenced by the clinical condition of the infant. This series demonstrates that a low mortality rate can be achieved with operative correction, even when infants are at point of death.

98 Spectrum of Cardiovascular Lesions in Mucocutaneous Lymph Node Syndrome: Analysis of Eight Cases

JUNICHIRO FUKUSHIGE, MICHAEL R. NIHILL and DAN G. McNAMARA

Eight additional cases of mucocutaneous lymph node syndrome with cardiovascular complications highlight the varied and diffuse cardiovascular lesions found in this syndrome. Four patients who died had aneurysms of the coronary arteries, usually associated with organizing thrombi. One patient required triple aortocoronary bypass surgery and one patient underwent excision of a brachial arterial aneurysm. Long-term follow-up of survivors of the acute stage is necessary to establish the spectrum of late complications and sequelae.

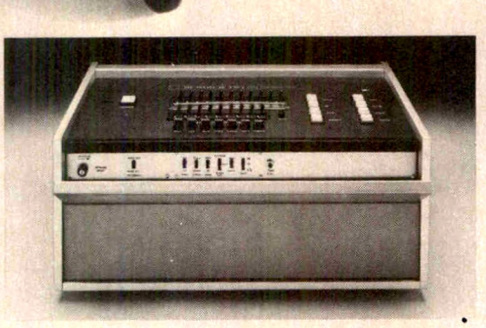
Burdick's answer to lower-cost computer-assisted ECG analysis.



If you've thought of using computer technology in your ECG practice, but delayed the decision because of cost, Burdick has a new, cost-effective way for you to add this useful and beneficial patient service.

Burdick's TR-1 ECG transmitter is the answer. It combines with the dependable, economical Burdick EK-5AS electrocardiograph. Result: a sophisticated, yet simple system that provides transmission of 3-channel information for computer-assisted analysis.

If you already have a Burdick EK-5AS, EK-5A with minor modification or other single-channel electrocardiograph, you can obtain computer analysis service with the easy addition of the TR-1. You get the benefits of 3-channel computer-assisted analysis with the simplicity of cost-saving, single-channel recording. With easy, push-button control, the TR-1 automatically dials the computer center and transmits 3-channel patient data over phone lines. Your EK-5AS starts recording, automatically sampling each lead for over-reading the computer analysis of the 3-channel patient data.

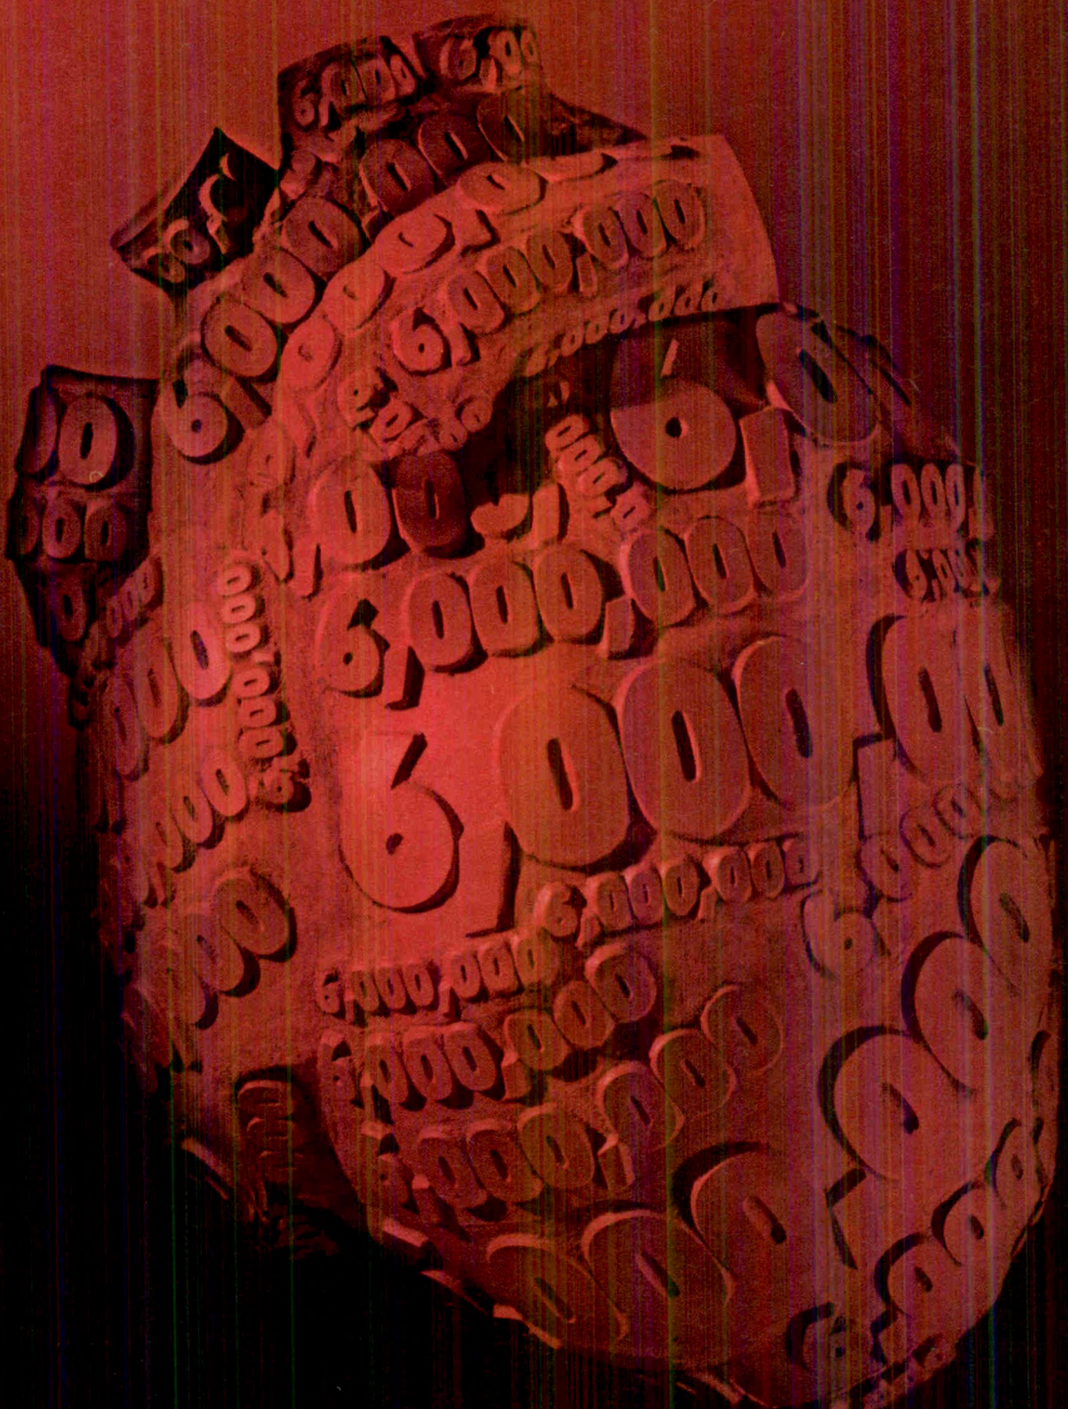
The combination of single-channel EK-5AS and TR-1 transmitter provides you with a low-cost, attractive and reliable matched system. The complete system is mounted in a mobile cart with phone handset and coupler.

For more information about this easy entry to specialized cardiology service, or a demonstration, call toll-free 800-356-0701. Within Wisconsin 608-868-7631.

The Burdick Corporation
Milton, Wisconsin 53563

BURDICK

6,000,000 fewer beats a year



Because of the way Inderal® (propranolol HCl) works, the anginal heart doesn't have to work so hard.

Consider the anginal heart at stress: It works harder, faster. Needs more oxygen. Pumps harder, faster still. Strives for more oxygen—with pain. Anginal attack means more nitroglycerin. And that means faster heart rate. The cycle repeats.

Consider Inderal: It reduces heart rate—therapeutically—by some 12 beats a minute.[1-6] 720 fewer beats per hour. Some 6 million fewer beats per year. That means less work for the anginal heart. Less oxygen demand by the myocardium. Fewer anginal attacks. Less need for sublingual nitroglycerin. More tolerance for exercise—and more freedom of action.

Reduction in heart rate is modest: should not be cause for concern.[7] The relatively low dosages required for angina prophylaxis (an average of 160 mg/day) produce few, if any, serious adverse reactions, which in any case are readily recognized and controlled.

With proper patient selection—in the absence of bronchial asthma, sinus bradycardia, or heart block greater than first degree—risk of precipitating cardiac failure is extremely rare. And withdrawal problems may be avoided by reducing dosage gradually—rather than abruptly.*

Consider too: There is also a favorable redistribution of perfusion to the vulnerable subendocardium.[8] And, in patients who may still need nitroglycerin p.r.n., INDERAL will cancel the undesirable increase in heart rate and contractility.

Prescribe INDERAL with confidence. Effective. Reliable. For patients with moderate to severe angina in whom conventional measures have failed.

*For full information on Contraindications, Precautions, Adverse Reactions, and Warnings, including avoidance of abrupt withdrawal, please consult the prescribing information on the following page.

Ayerst

INDERAL® (PROPRANOLOL HCl)
TODAY'S 40mg 80mg tabs.
BENCHMARK FOR ANGINA PROPHYLAXIS

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® BRAND OF
PROPRANOLOL HYDROCHLORIDE
A beta-adrenergic blocking agent

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

ACTIONS

Beta receptor blockade is useful in conditions in which, because of pathologic or functional changes, sympathetic activity is excessive or inappropriate and detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

The proper objective of beta blockade therapy is to decrease adverse sympathetic stimulation but not to the degree that may impair necessary sympathetic support.

Propranolol may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to decreased oxygen requirement.

INDICATION

Angina Pectoris Due to Coronary Atherosclerosis: The initial treatment of angina pectoris involves weight control, rest, cessation of smoking, use of sublingual nitroglycerin, and avoidance of precipitating circumstances. INDERAL is indicated in selected patients with moderate to severe angina pectoris who have not responded to these conventional measures. Propranolol should not be used in patients with angina which occurs only with considerable effort or with infrequent precipitating factors.

INDERAL exerts both favorable and unfavorable effects, the preponderance of which may be beneficial. (See ACTIONS Section.) INDERAL should not be continued unless there is reduced pain or increased work capacity.

Because of the potential for adverse results, treatment should be carefully monitored. The patient should also be reevaluated periodically since the dosage requirement and the need to continue INDERAL may be altered by clinical exacerbations or remissions. (See DOSAGE AND ADMINISTRATION.)

Additional studies of the effects of INDERAL in angina pectoris patients are in progress to better evaluate and define the proper role of INDERAL in this condition.

CONTRAINDICATIONS

INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.*, that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by INDERAL's negative inotropic effect. The effects of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, INDERAL therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.*, isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to keep in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. Embryotoxic effects have been seen in animal studies at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress

Respiratory: bronchospasm

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura

Miscellaneous: reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been conclusively associated with propranolol.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase

DOSAGE AND ADMINISTRATION

The dosage range for INDERAL is different for each indication.

ORAL

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 10-20 mg three or four times daily, before meals and at bedtime, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg per day. In angina pectoris, the value and safety of dosage exceeding 320 mg per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of several weeks. (See WARNINGS.)

PEDIATRIC DOSAGE

At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

OVERDOSAGE OR EXAGGERATED RESPONSE

IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg): IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS

HYPOTENSION—VASOPRESSORS, *e.g.*, LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE

HOW SUPPLIED

INDERAL

TABLETS (propranolol hydrochloride)

No. 461—Each scored tablet contains 10 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 462—Each scored tablet contains 20 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 464—Each scored tablet contains 40 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 468—Each scored tablet contains 80 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

INJECTABLE

No. 3265—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 ml ampuls in boxes of 10.

108 **The Surgical Decision in Tetralogy of Fallot: Weighing Risks and Benefits With Decision Analysis**

ARTHUR GARSON, Jr., G. ANTHONY GORRY, DAN G. McNAMARA and DENTON A. COOLEY

Decision analysis was used to assess the risks and benefits of three courses of action in the symptomatic infant with tetralogy of Fallot: (1) primary intracardiac repair; (2) palliative operation in infancy and delayed intracardiac repair; and (3) treatment with propranolol in infancy and delayed repair. The choice of action was affected most by the mortality of primary intracardiac repair and the likelihood of a good hemodynamic result. If operative mortality rate from intracardiac repair is 10 percent or less intracardiac repair should be performed. Otherwise, propranolol therapy with delay of intracardiac repair should be selected.

117 **Absent Right Superior Vena Cava With Persistent Left Superior Vena Cava: Implications and Management**

CORA C. LENOX, JAMES R. ZUBERBUHLER, SANG C. PARK, WILLIAM H. NECHES, ROBERT A. MATHEWS, F. JAY FRICKER, HENRY T. BAHNSON and RALPH D. SIEWERS

Seven cases of absent right superior vena cava and normal situs were diagnosed at Children's Hospital of Pittsburgh where an incidence rate of 0.1 percent was found among 4,825 cardiac catheterizations performed between July 1966 and June 1978. Other associated cardiac defects were present in these patients and arrhythmias may be encountered. This anomaly should be suspected clinically when the chest roentgenogram reveals absence of the shadow of the right superior vena cava and shows an extra structure in the area of the aortic knob and upper mediastinum. The diagnosis may be confirmed with contrast and radionuclide angiocardiography. Any patient with this anomaly who requires an artificial pacemaker should have the epicardial type because of the difficulty in obtaining capture with a transvenous pacemaker.

REPORTS ON THERAPY

123 **Sustained Beneficial Effects of Oral Amrinone on Cardiac and Renal Function in Patients With Severe Congestive Heart Failure**

THIERRY H. LeJEMTEL, EDMUND KEUNG, HILLEL S. RIBNER, RICHARD DAVIS, JOHN WEXLER, M. DONALD BLAUFOX and EDMUND H. SONNENBLICK

This study of the hemodynamic and renal effects of orally administered amrinone (50 to 300 mg) in 10 patients with advanced congestive heart failure showed an increase in cardiac index from 1.56 ± 0.41 to 2.20 ± 0.43 liters/min per m^2, a decrease in pulmonary wedge pressure from 26.1 ± 5.7 to 17.0 ± 5.7 mm Hg, in arterial pressure from 86.0 ± 8.4 to 81.3 ± 7.7 mm Hg and in systemic vascular resistance from 2,406 ± 603 to 1,693 ± 261 dynes sec cm^{-5}. Both effective renal blood flow and glomerular filtration fraction increased significantly and were associated with a concomitant rise in cardiac index. These and other measurements demonstrate the cardiotonic efficacy of amrinone in human subjects and recommend its further investigation as a therapeutic agent for the continued treatment of congestive heart failure. The improvement in ventricular performance induced by amrinone in patients with heart failure appears to result from a direct stimulation of the depressed myocardium and a decrease in peripheral vascular resistance. Thrombocytopenia developed in two patients.

130 **Use of Ajmaline In Patients With the Wolff-Parkinson-White Syndrome to Disclose Short Refractory Period of the Accessory Pathway**

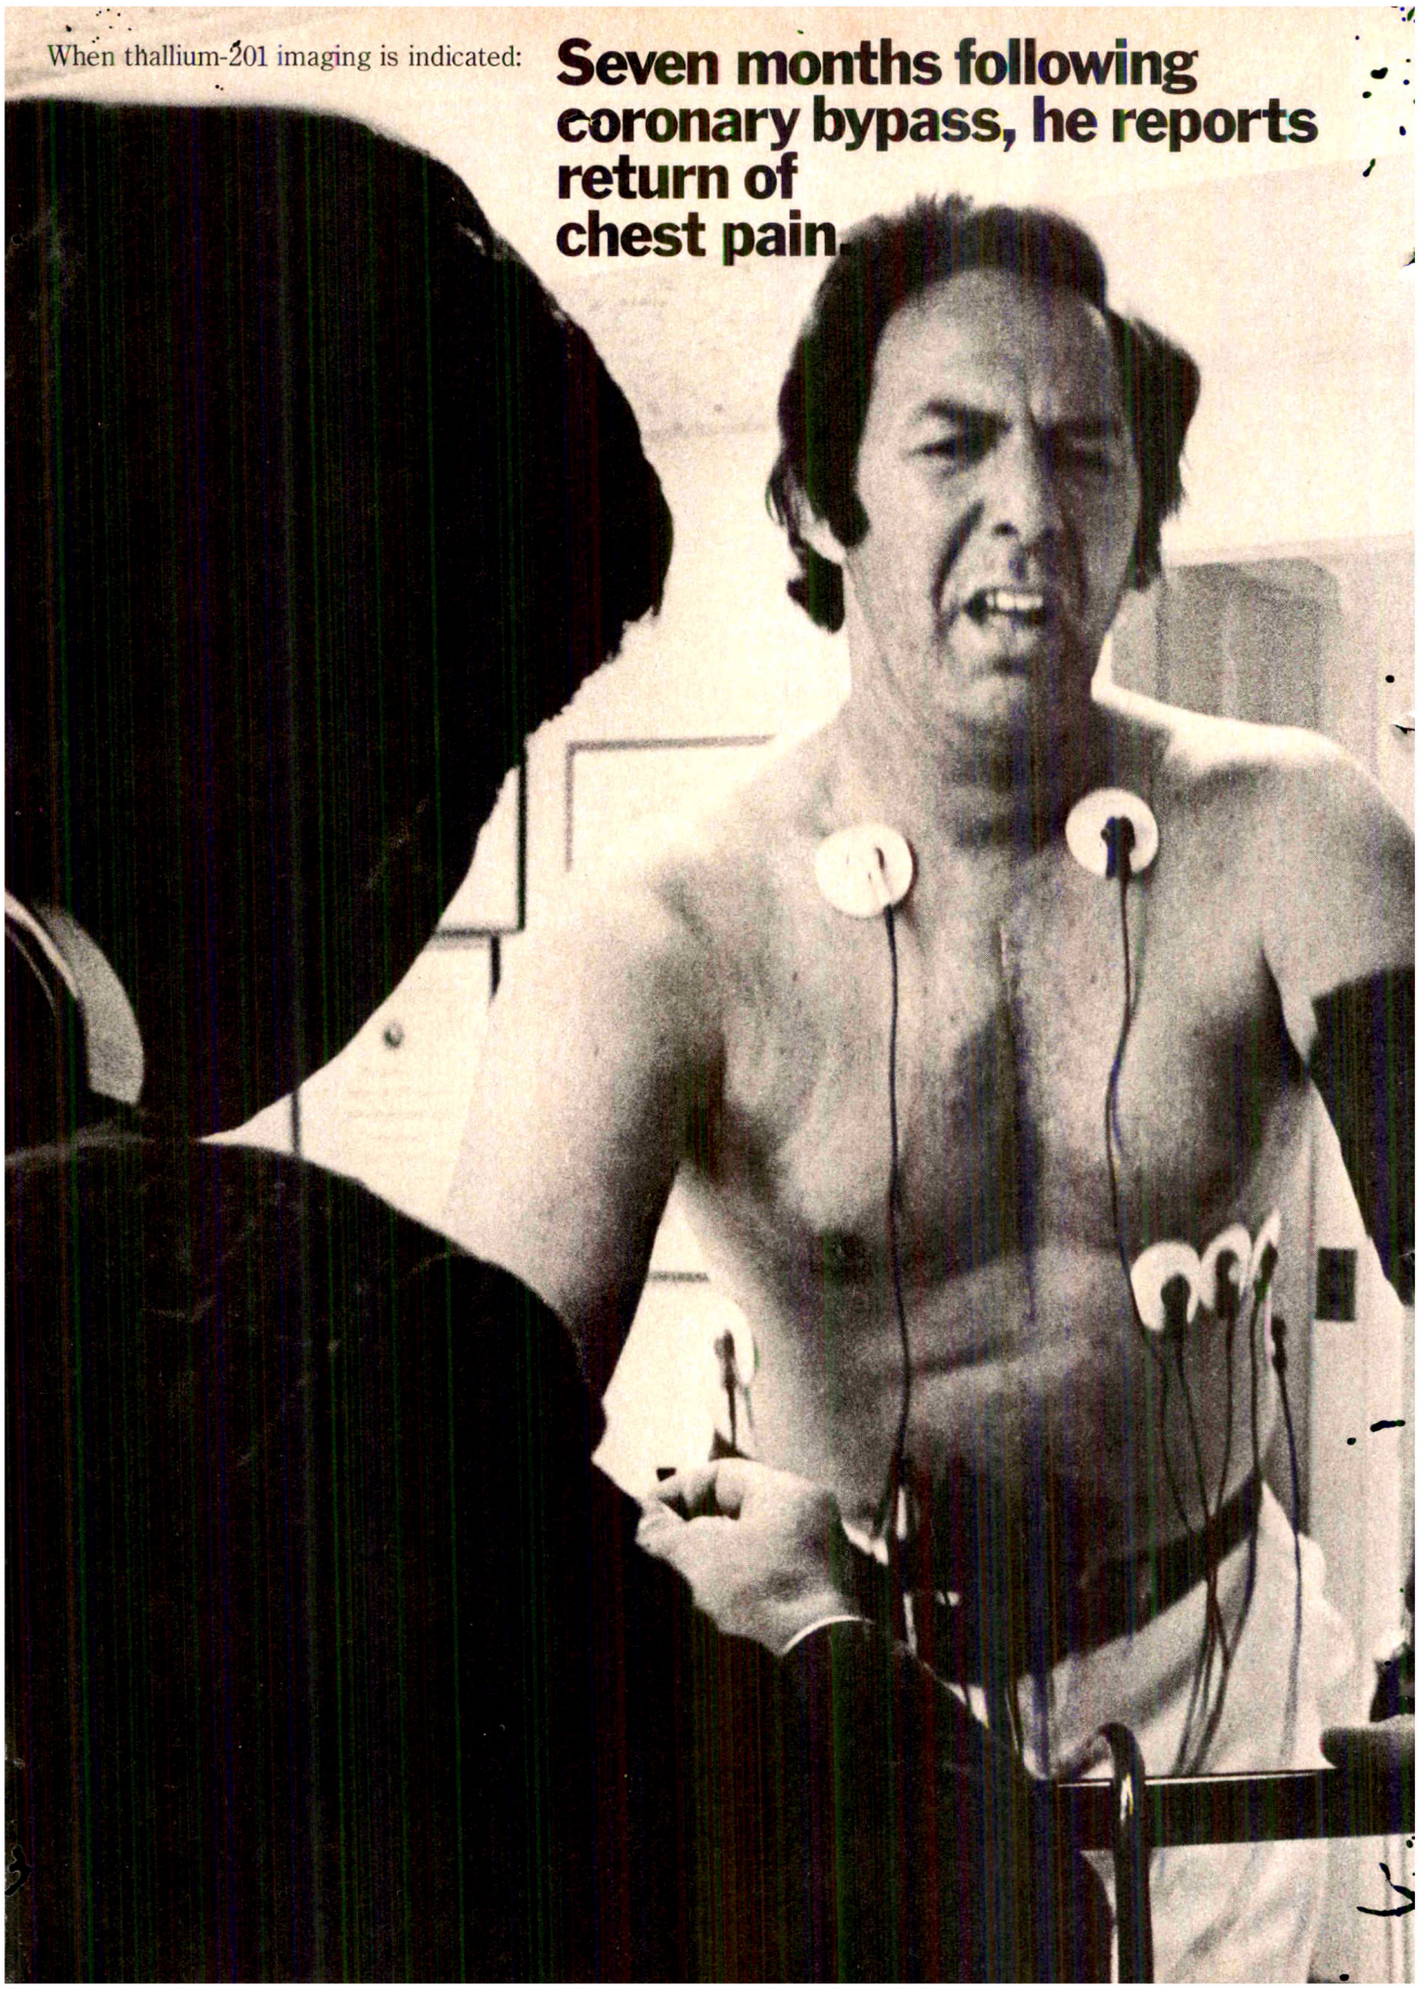
HEIN J. J. WELLENS, FRITS W. BÄR, ANTON P. GORGELS and EDUARD J. VANAGT

Intravenously administered ajmaline (50 mg over a 3 minute period) produced complete anterograde block in the accessory pathway of 32 of 59 patients with the Wolff-Parkinson-White syndrome. Ajmaline, a reserpine deriva-

Continued on page A34

When thallium-201 imaging is indicated:

Seven months following coronary bypass, he reports return of chest pain.



As the population of successful coronary bypass patients continues to grow, physicians will encounter an increasing number who report a return of chest pain after varying postoperative periods.

Complaints of chest pain in post-bypass patients deserve thorough, progressive workup... usually including exercise electrocardiography. Without exercise ECG evidence of myocardial ischemia, the clinician must decide on symptoms alone whether or not to suggest repeat coronary angiography. In such a setting, myocardial perfusion imaging with thallium-201 may rule out—or confirm—the possibility of electrically silent graft occlusion or extension of disease.

Localizes in perfused myocardium

Thallium-201 is a radioactive isotope that, following intravenous injection, distributes within myocardial cells in proportion to regional perfusion. Nuclear medicine imaging performed following injection will display relative regional perfusion and myocardial cell viability.

When used in conjunction with stress electrocardiography, thallium-201 has proven successful in demonstrating regional ischemia that may escape detection by ECG. A region that appears "cold" following exercise and injection, but "fills in" on repeat imaging a few hours later, suggests stress ischemia secondary to fixed stenosis that restricts perfusion during exercise. A region that remains persistently "cold" generally indicates irreversible myocardial scarring.

Reveals graft patency/occlusion

Many institutions routinely perform preoperative and postoperative stress thallium studies to obtain functional evidence of graft-mediated reperfusion of formerly ischemic regions. This sequence of studies can serve as a valuable baseline in the event that the patient returns with a complaint of chest pain:

- If a repeat thallium study discloses ischemia in the regions formerly perfused by the grafts, occlusion may be suspected.
- If the repeat study suggests new areas of ischemia, progression of atherosclerotic disease may have occurred.
- If the repeat study is essentially unchanged from the postoperative findings, nonischemic etiology should be explored.

Useful with/without baseline

Even if baseline stress-thallium studies are not available, this procedure can still provide valuable diagnostic guidance—particularly if it is negative, or displays clear evidence of ischemia in the grafted regions.

Information, teaching program available

New England Nuclear offers an extensive range of journal reprints on the use of thallium-201 imaging, and provides teaching rounds material and reference monographs at no charge, as a service to the profession. For more information on thallium-201, use the coupon below, or call **800-225-1572, ext 2234** toll free.

Thallous Chloride Tl 201

For Diagnostic Use

November 1977

Indications and Usage: Thallous Chloride Tl 201 may be useful in myocardial perfusion imaging for the diagnosis and localization of myocardial infarction. It may also be useful in conjunction with exercise stress testing as an adjunct in the diagnosis of ischemic heart disease (atherosclerotic coronary artery disease).

Contraindications: None known.

Warnings: In studying patients in whom myocardial infarction or ischemia is known or suspected, care should be taken to assure continuous clinical monitoring and treatment in accordance with safe, accepted procedure. Exercise stress testing should be performed only under the supervision of a qualified physician and in a laboratory equipped with appropriate resuscitation and support apparatus.

Ideally, examinations using radiopharmaceutical drug products—especially those elective in nature—of women of childbearing capability should be performed during the first ten days following the onset of menses.

Precautions: Data are not available concerning the effect of marked alterations in blood glucose, insulin, or pH (such as is found in diabetes mellitus) on the quality of thallium Tl 201 scans. Attention is directed to the fact that thallium is a potassium analog, and since the transport of potassium is affected by these factors, the possibility exists that the thallium may likewise be affected.

Thallous Chloride Tl 201, as all radioactive materials, must be handled with care and used with appropriate safety measures to minimize external radiation exposure to clinical personnel. Care should also be taken to minimize radiation exposure to patients in a manner consistent with proper patient management.

No long-term animal studies have been performed to evaluate carcinogenic potential.

Adequate reproduction studies have not been performed in animals to determine whether this drug affects fertility in males or females, has teratogenic potential, or has other adverse effects on the fetus. Thallous Chloride Tl 201 should be used in pregnant women only when clearly needed.

It is not known whether this drug is excreted in human milk. As a general rule nursing should not be undertaken when a patient is administered radioactive material.

Safety and effectiveness in children have not been established.

Adverse Reactions: Adverse reactions related to use of this agent have not been reported to date.

Dosage and Administration: The recommended adult (70kg) dose of Thallous Chloride Tl 201 is 1-1.5mCi. Thallous Chloride Tl 201 is intended for intravenous administration only.

For patients undergoing resting thallium studies, imaging is optimally begun within 10-20 minutes after injection. Several investigators have reported improved myocardial-to-background ratios when patients are injected in the fasting state, in an upright posture, or after briefly ambulating.

Best results with thallium imaging performed in conjunction with exercise stress testing appear to be obtained if the thallium is administered when the patient reaches maximum stress and when the stress is continued for 30 seconds to one minute after injection. Imaging should begin within ten minutes post-injection since target-to-background ratio is optimum by that time. Several investigators have reported significant decreases in the target-to-background ratios of lesions attributable to transient ischemia by two hours after the completion of stress testing.

The patient dose should be measured by a suitable radioactivity calibration system immediately prior to administration.

Radiopharmaceuticals should be used by persons with specific training in the safe use and handling of radionuclides produced by nuclear reactor or particle accelerator and whose experience and training have been approved by the appropriate government agencies authorized to license the use of radionuclides.

How Supplied: Thallous Chloride Tl 201 for intravenous administration is supplied as a sterile, non-pyrogenic solution containing at calibration time, 1mCi/ml of Thallous Tl 201, 9mg/ml sodium chloride, and 9mg/ml of benzyl alcohol. The pH is adjusted to between 4.5-6.5 with hydrochloric acid and/or sodium hydroxide solution. Vials are available in the following quantities of radioactivity: 1.5, 3.0, 4.5, 6.0, and 9.0 millicuries of Thallous Tl 201.

The contents of the vial are radioactive. Adequate shielding and handling precautions must be maintained.

KATO®

(potassium chloride for oral solution)

20 mEq (1.5 g. KCl)

Prescribing Information

DESCRIPTION:
Spray-dried tomato powder containing 20 mEq potassium (equivalent to 1.5 g. KCl) per 6 grams powder (one dose) with natural and synthetic flavors, spices and colors. Benzoic acid and potassium benzoate added as preservatives. When reconstituted as directed, makes a pleasantly flavored, low sodium tomato juice drink. Each daily dose (2 packets) contains less than 10 mg. sodium.

INDICATIONS:
The prevention or correction of potassium deficit, particularly when accompanied by hypochloremic alkalosis in conjunction with thiazide diuretic therapy, in digitalis intoxication, or as the result of long-term corticosteroid therapy, low dietary intake of potassium, or excessive vomiting or diarrhea.

CONTRAINDICATIONS:
Potassium is contraindicated in severe renal impairment involving oliguria, anuria or azotemia; in untreated Addison's disease, familial periodic paralysis, acute dehydration, heat cramps, hyperkalemia from any cause. Potassium chloride should not be employed in patients receiving potassium-sparing agents such as aldosterone antagonists and triamterene.

PRECAUTIONS:
KATO is a concentrate and should be taken only after reconstituting with water as directed. This preparation, like other potassium supplements, must be properly diluted to avoid the possibility of gastrointestinal irritation. Do not use in patients with low urinary output or renal decompensation. Administer with caution; it is impossible to assess accurately the daily dose required. Excessive dosage may result in potassium intoxication. Frequent checks of the clinical status of the patient, ECG and/or plasma potassium level should be made. High plasma concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease.

ADVERSE REACTIONS:
Vomiting, diarrhea, nausea, and abdominal discomfort may occur. Gross overdosage may produce signs and symptoms of potassium intoxication: mental confusion, listlessness, paresthesia of the extremities, weakness and heaviness of legs, flaccid paralysis, hyperkalemia, ECG abnormalities, fall in blood pressure, cardiac arrhythmias and heart block. The characteristic changes in the ECG are disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, tall peaked T waves, etc.

TOXICITY:
Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

TREATMENT OF HYPERKALEMIA:
1. Dextrose solution 10% or 25% containing 10 units of crystalline insulin per 20 g. dextrose, given I.V. in a dose of 300cc to 500cc in an hour. 2. Adsorption and exchange of potassium using sodium or ammonium cycle cation exchange resin, orally or as retention enema. 3. Hemodialysis or peritoneal dialysis. 4. Elimination of potassium-containing foods and medicaments. Warning: Digitalis toxicity can be precipitated by lowering the plasma potassium concentration too rapidly in digitalized patients.

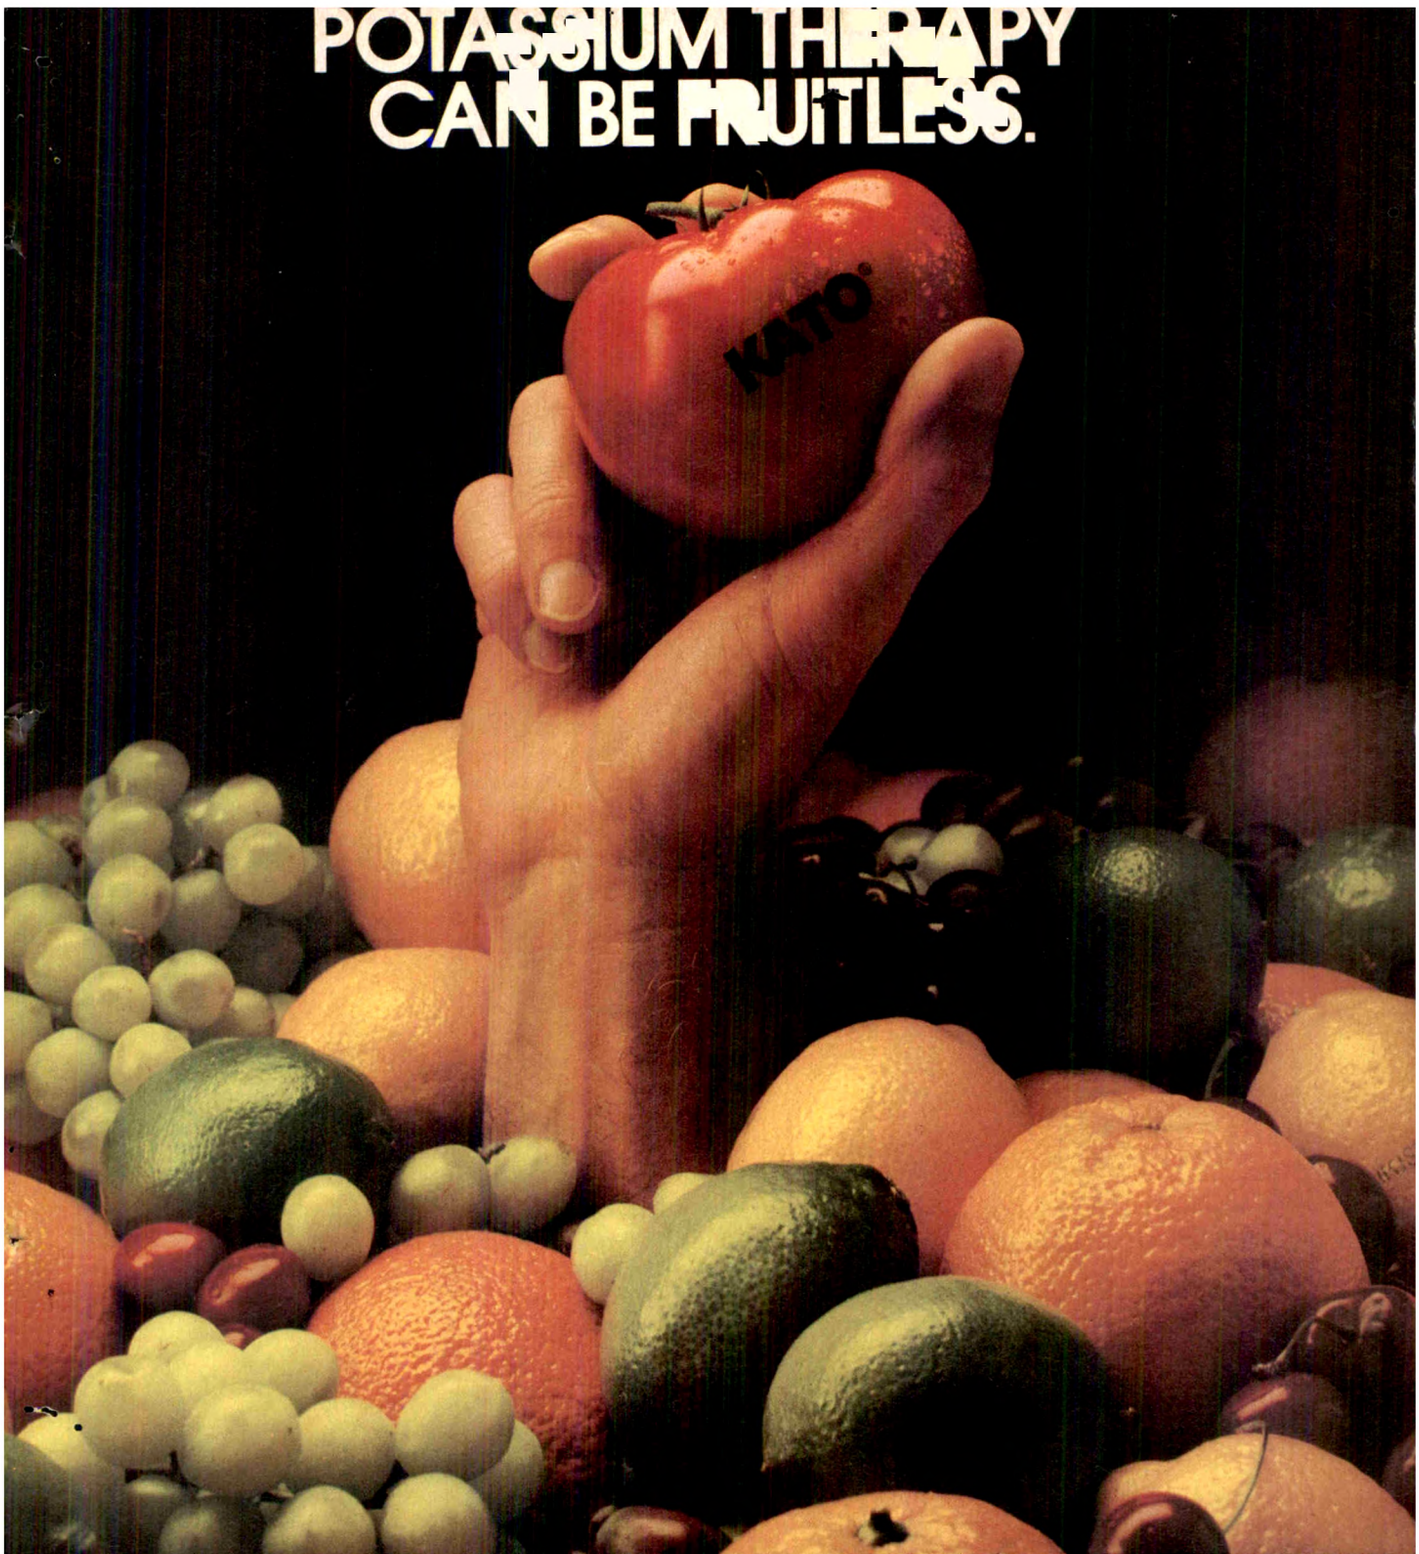
ADMINISTRATION AND DOSAGE:
Mix with water to make a pleasant tomato juice drink. Each 6 gram unit dose packet provides 20 mEq of potassium. Usual adult dose—1 packet of KATO mixed with about 2 ounces of water twice daily—supplies 40 mEq potassium per day. Take with meals or follow with ½ glass of water. Larger doses may be required, but should be administered under close supervision because of the possibility of potassium intoxication.

HOW SUPPLIED:
Cartons of 30 and 120 6 gram unit dose packets, 20 mEq each.

02-488-30
1-79

SYNTEX
SYNTEX PUERTO RICO, INC.
HUMACAO, PUERTO RICO 00661

POTASSIUM THERAPY CAN BE FRUITLESS.



Trying to smother the taste of potassium with sweet fruit flavorings never seems to work very well. It's like pouring salt straight into your orange juice—and just about as undrinkable for many patients. That's when a matter of taste becomes a problem of compliance.

KATO® (potassium chloride for oral solution) has the right kind of taste, the fresh tomato tang that [illegible] saltiness of potassium chloride.

It provides the potassium salt of choice—the chloride—as a powder that mixes quickly with water, for the liquid dosage form preferred for safety. Each easy-to-use packet contains 20 mEq potassium chloride, with less than 5 mg sodium.

Offer your patients the tangy taste of KATO—the fruitless [illegible]

KATO®

SYNTEX PUERTO RICO, INC.
HUMACAO, PUERTO RICO 00661

tive, prolongs briefly the effective refractory period of the accessory pathway in patients with this syndrome. If no anterograde block in the accessory pathway develops after ajmaline administration, a short (less than 270 msec) duration of the effective refractory period of the accessory pathway in the anterograde direction is likely. This test appears to be a reliable and rapid procedure to identify those patients with this syndrome who have a short refractory period of the accessory pathway and who are at possible risk of circulatory insufficiency or sudden death if atrial fibrillation occurs. Because complete anterograde block of the normal A-V pathway may be present in the patient with an accessory A-V connection, the procedure should be performed under well controlled hospital conditions.

134 **Surgical Versus Medical Therapy for Treatment of Unstable Angina: Changes in Work Status and Family Income**

RICHARD O. RUSSELL, Jr., JOHN B. WAYNE, JENNIE KRONENFELD, EDGAR D. CHARLES, ALBERT OBERMAN, NICHOLAS T. KOUCHOUKOS, CHARLES WHITE, WILLIAM ROGERS, JOHN A. MANTLE and CHARLES E. RACKLEY

These results confirm that patients who are successfully managed on medical therapy for unstable angina pectoris return to full-time employment at a significantly higher rate than those who undergo bypass surgery (both initially and late). Patients who have income from sources other than their own work or the work of their spouses are least likely to return to full-time employment, regardless of the work status of the spouse. Those who were making higher income are less likely to return to work. Patients who initially underwent bypass surgery had the greatest decrease in family income and were the least likely to return to full-time employment. The changes in annual family income were + $1,111 for medical patients, − $2,447 for surgical patients and + $875 for those later undergoing surgery. Changes in family income were related to a large number of variables discussed in this article.

REVIEWS

141 **Hypertrophic Cardiomyopathy: Recent Observations Regarding the Specificity of Three Hallmarks of the Disease: Asymmetric Septal Hypertrophy, Septal Disorganization and Systolic Anterior Motion of the Anterior Mitral Leaflet**

BARRY J. MARON and STEPHEN E. EPSTEIN

In an analysis of more than 1,600 patients with hypertrophic cardiomyopathy, the specificity of asymmetric hypertrophy, marked septal disorganization and systolic anterior motion of the anterior mitral leaflet was at least 90 percent (90, 93 and 97 percent, respectively). These data suggest that most patients with these basic anatomic criteria for hypertrophic cardiomyopathy have a distinct disease entity with diverse clinical manifestations. The majority of such patients appear to have a genetically transmitted disease. Echocardiographic evaluation of family members showing an abnormal septal/free wall thickness ratio in one or more relatives suggests the presence of a primary cardiomyopathy in the suspected case.

DIAGNOSTIC SHELF

155 **Intracardiac Flow Pattern in Mitral Regurgitation Studied With Combined Use of the Ultrasonic Pulsed Doppler Technique and Cross-Sectional Echocardiography**

KUNIO MIYATAKE, NAOKAZU KINOSHITA, SEIKI NAGATA, SHINTARO BEPPU, YUNG-DAI PARK, HIROSHI SAKAKIBARA and YASUHARU NIMURA

In this study of 30 patients with mitral regurgitation proved with left ventriculography, the combination of the ultrasonic pulsed Doppler technique and cross-sectional echocardiography proved useful in the detection and analysis of regurgitant flow. In the left atrial cavity, abnormal Doppler signals recorded during systole were bidi-

For the special needs of patients with hard, dry stools

SENOKOT®-S

(standardized senna concentrate and dioctyl sodium sulfosuccinate) **Tablets**

the "S" stands for softener

For patients with hard, dry stools
Hard, dry stools hurt, and may be hazardous by causing straining. SENOKOT-S Tablets offer comfortable relief by softening the stool *and* stimulating its movement.

Provides standardized senna concentrate, a clinically established laxative of choice
Standardized senna concentrate is a gentle, effective neuroperistaltic stimulant with documented effectiveness in thousands of patients. Its virtually colon-specific, gentle, predictable action is generally free of side effects at proper dosage levels.

Provides DSS, the classic stool softener
DSS in SENOKOT-S Tablets complements the laxative effect of standardized senna concentrate by "moistening" and softening the stool for smoother and easier passage.

Comfortable overnight action
With DSS and standardized senna concentrate, SENOKOT-S Tablets provide *both* softness and stimulation for constipated patients with hard, dry stools. Taken at bedtime, SENOKOT-S Tablets usually induce predictable, comfortable evacuation the next morning.

hypertension

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose or three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

667292 (8/79) C79-22

Time is the test of all things.

1954
1980

BRIEF SUMMARY

Kaon® Elixir (potassium gluconate) Grape or Lemon-Lime Flavors
Sugar-Free

Description: Each 15 ml (tablespoonful) supplies 20 mEq of elemental pot (as potassium gluconate, 4.68 g) with saccharin and aromatics. Alcohol 5%,

Indications: Kaon Elixir is indicated for the treatment of potassium depleti patients with hypokalemia and for the treatment of digitalis intoxication. Ka Elixir is also indicated for the prevention of potassium depletion when the di intake of potassium is inadequate for this purpose. The prophylactic administ of potassium ion may be indicated in patients receiving digitalis and diuretics f treatment of congestive heart failure; hepatic cirrhosis with ascites; patients wit hypertension on long-term diuretic therapy; patients on corticosteroid therapy; hyperaldosteronism states with normal renal function; the nephrotic syndrome; ar certain diarrheal states.

Contraindications: Potassium supplements are contraindicated in patients with hy kalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: C renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissu breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sp diuretic (e.g. spironolactone, triamterene).

Warnings: Do not administer full strength. Kaon Elixir may cause gastrointestinal irritation if ac tered undiluted. For details regarding adequate dilution, see Dosage and Administration.

In patients with impaired mechanisms for excreting potassium, the administration of potassium sal produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia ca develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g. spironolactone or triamterene) since the simultaneou administration of these agents can produce severe hyperkalemia.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acut alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentr tion into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electr cardiogram, and the clinical status of the patient.

In hypokalemic states, especially in patients on a low-salt diet, hypochloremic alkalosis is a possibility that may require chloride as well as potassium supplementation. In these circumstances, potassium replacement with potassium chloride (e.g. Kaochlor 10% Liquid, W-T) may be more advantageous than with other potassium salts. Howev Kaon can be supplemented with chloride. Ammonium chloride is an excellent source of chloride ion (18.7 mEq per gram) but it should not be used in patients with hepatic cirrhosis where ammonium salts are contraindicated.

Adverse Reactions: Nausea, vomiting, diarrhea, and abdominal discomfort have been reported. The symptoms and signs of potassium intoxication include paresthesias of the extremities, flaccid paralysis, listlessness, mental confusion, weakness and heav iness of the legs, fall in blood pressure, cardiac arrhythmias, and heart block.

Overdosage: The administration of oral potassiu salts to persons with normal excretory mechanism for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, po tentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by a increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

How Supplied: Pints and gallons in Grape and Lemon-Lime flavors; 15 m Stat-Pak® and 4 fl. oz. in Grape flavor only.

rectional or unidirectional and of a wide velocity range. Mapping on the cross-sectional echocardiogram of the area in which these signals occurred revealed the main direction of regurgitant flow as documented with angiography. In the mitral area the abnormal signals were powerful and of a wide velocity range. These signals may reflect both mitral regurgitant flow and the vibration of the mitral valve.

CASE REPORTS

163 Infiltrative Cardiomyopathy With Conduction Disease and Ventricular Arrhythmia: Electrophysiologic and Pathologic Correlations

SAROJA BHARATI, MAURICE LEV, PABLO DENES, JAMES MODLINGER, CHRISTOPHER WYNDHAM, ROBERT BAUERNFEIND, MELVIN GREENBLATT and KENNETH M. ROSEN

Although conduction defects, ventricular arrhythmias and sudden death are known complications of infiltrative cardiomyopathy, this report provides close correlation among the electrocardiographic, electrophysiologic and pathologic findings in a 34 year old man with cardiac sarcoidosis and in a 53 year old man with cardiac amyloidosis and ventricular tachycardia. These data support the value of extensive noninvasive and invasive diagnostic studies in patients with serious, apparently primary arrhythmias, including extracardiac or cardiac biopsy to establish definitive diagnosis of the specific cardiomyopathic process. Such a demonstration might allow specific therapeutic interventions in addition to the usual antiarrhythmic therapy.

174 Cough-Facilitated Conversion of Ventricular Tachycardia

JEANNE Y. WEI, H. LEON GREENE and MYRON L. WEISFELDT

A series of abrupt forceful coughs on command proved effective in converting 33 episodes of drug-refractory ventricular tachycardia to sinus rhythm in a 64 year old man with hypertension and two previous myocardial infarctions. Whenever the patient was unable to cough as directed, both chest thump and external countershock were required daily. Although several mechanisms may be involved, it is still unclear how the cough converts ventricular tachycardia to normal sinus rhythm. Coughing was also successful in two other patients with ventricular tachycardia that occurred after injection of intracoronary contrast medium in the cardiac catheterization laboratory.

The heart of the matter in hypertension is the kidney

The kidney—not the heart—is the key to long-term arterial pressure control. Diuretics help the kidney excrete sodium, reduce fluid volume and lower blood pressure.

No diuretic blocks sodium retention longer than Hygroton.

In mild hypertension low-dose Hygroton 25 mg. An effective, conservative therapy.

In mild hypertension

Low-dose

Hygroton® 25 mg. one a day

(chlorthalidone USP)

Gets to the heart of the matter...simply

BRIEF SUMMARY

Indications: Hypertension, adjunctive therapy in edema.

Contraindications: Anuria, hypersensitivity to chlorthalidone or other sulfonamide-derived drugs.

Warnings: Should be used with caution in severe renal disease, impaired hepatic function or progressive liver disease. May add to or potentiate the action of other antihypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. There is a possibility of exacerbation or activation of systemic lupus erythematosus with thiazides, which are related to chlorthalidone. This has not been reported with chlorthalidone. Thiazides cross the placental barrier and appear in cord blood. Use in pregnant women requires that the anticipated benefits of the drug be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier and appear in breast milk. If use of the drug is essential, the patient should stop nursing.

Precautions: Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather. Hyperuricemia may occur or gout be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes mellitus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy. Chlorthalidone and related drugs may decrease serum PBI levels without signs of thyroid disturbance.

Adverse Reactions: Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis; dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn.

Usual Dose: One tablet daily.

How Supplied: Tablets—100 mg. (white, scored), 50 mg. (aqua) and 25 mg. (peach) in bottles of 100 and 1000; unit-dose blister packs, boxes of 100 (10 x 10 strips). Also, 100 mg. and 50 mg. in PAKs of 28 tablets, boxes of 6.

Duraquin®
(QUINIDINE GLUCONATE TABLETS)

sustained-release tablets, 330 mg

Brief summary of prescribing information
DURAQUIN® (quinidine gluconate tablets) Sustained Release

CLINICAL PHARMACOLOGY: In clinical studies, single doses of Duraquin produced a mean maximum plasma level at 2 hours which was maintained for 12 hours. This broad plateau indicates slow, continuous absorption from the gastrointestinal tract.

In multiple dose studies, administration of Duraquin tablets, 660 mg every 12 hours, produced steady state (equilibrium) plasma levels shortly after 24 hours. The average quinidine plasma levels (Cramer and Isaksson assay[1]) were 0.81 mcg/ml and the mean peak levels were 1.16 mcg/ml in a group of normal male subjects weighing 75 Kg. Following the last dose at steady state, quinidine plasma levels decreased at an approximate rate of 50% in 10 hours. This compares to the expected plasma half-life of 6.3 hours for quinidine sulfate tablets, USP.

Therapeutic and toxic effects coordinate better with plasma levels than with dosage. While therapeutic levels of 3 to 6 mcg/ml with a range of 1.5 to 9 mcg/ml have been reported, these values are based on peak plasma levels determined by the less specific Edgar and Sokolow assay[2] This procedure yields quinidine levels averaging 22% higher than the Cramer and Isaksson assay. Plasma levels vary considerably in patients receiving identical doses. Therefore, it is advisable to adjust the dosage by monitoring plasma quinidine levels.

INDICATION: Duraquin tablets are indicated for the prevention of premature atrial, nodal, or ventricular contractions. They are also indicated for the maintenance of normal sinus rhythm following spontaneous reversion or electrical conversion of atrial, nodal, or ventricular tachycardia, atrial flutter and fibrillation (either paroxysmal or chronic).

[1]Cramer, G. and Isaksson, B. Quantitative Determination of Quinidine in Plasma. Scandinavian J. Clin. & Lab. Investigation 15, 553, 1963.
[2]Edgar, A.L. and Sokolow, M. Experiences with the Photofluorometric Determination of Quinidine in Blood. J. Lab. Clin. Med. 36, 478, 1950.

CONTRAINDICATIONS: 1. History of hypersensitivity to quinidine manifested by thrombocytopenia, skin eruption, febrile reactions, etc.
2. Complete A-V block.
3. Complete bundle branch block or other severe intraventricular conduction defects exhibiting marked QRS widening or bizarre complexes.
4. Myasthenia gravis.
5. Arrhythmias associated with digitalis toxicity.

WARNINGS: 1. (a) In the treatment of atrial fibrillation with rapid ventricular response, ventricular rate should be controlled with digitalis glycosides *prior* to administration of quinidine.
(b) In the treatment of atrial flutter with quinidine, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine.

Recent reports have described increased, potentially toxic, digoxin plasma levels when quinidine is administered concurrently. When concurrent use is necessary, digoxin dosage should be reduced and plasma concentration should be monitored and patients observed closely for digitalis intoxication.
2. Quinidine cardiotoxicity may be manifested by increased PR and QT intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia. Appearance of these toxic signs during quinidine administration mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. Note: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia.
3. "Quinidine Syncope" may occur as a complication of long-term therapy. It is manifested by sudden loss of consciousness and ventricular arrhythmias with bizarre QRS complexes. This syndrome does not appear to be related to dose or plasma levels but occurs more often with prolonged QT intervals.

Duraquin®
(QUINIDINE GLUCONATE TABLETS) sustained-release tablets, 330 mg

Brief summary continued from previous page.

4. Because quinidine antagonizes the effect of vagal excitation upon the atrium and the A-V node, the administration of parasympathomimetic drugs (choline esters) or the use of any other procedure to enhance vagal activity may fail to terminate paroxysmal supraventricular tachycardia in patients receiving quinidine.
5. Quinidine should be used with extreme caution in:
a) The presence of incomplete A-V block, since a complete block and asystole may result. Quinidine may cause unpredictable abnormalities of rhythm in digitalized hearts. Therefore, it should be used with caution in the presence of digitalis intoxication (see 1. (b) above).
b) Partial bundle branch block.
c) Severe congestive heart failure and hypotensive states due to the depressant effects of quinidine on myocardial contractility and arterial pressure.
d) Poor renal function, especially renal tubular acidosis, because of the potential accumulation of quinidine in plasma leading to toxic concentrations.

PRECAUTIONS:

1. Test Dose—A preliminary test dose of a single tablet of quinidine *sulfate* should be administered prior to the initiation of the sustained release gluconate to determine whether the patient has an idiosyncrasy to the Quinidine molecule.
2. Hypersensitivity—During the first weeks of therapy, hypersensitivity to quinidine, although rare, should be considered (eg, angioedema, purpura, acute asthmatic episode, vascular collapse).
3. Long-Term Therapy—Periodic blood counts and liver and kidney function tests should be performed during long-term therapy and the drug should be discontinued if blood dyscrasias or signs of hepatic or renal disorders occur.
4. Large Doses—ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered.
5. Usage in Pregnancy—The use of quinidine, in pregnancy, should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus.
6. Nursing Mothers—The drug should be used with extreme caution in nursing mothers because the drug is excreted in breast milk.
7. General—In patients exhibiting asthma, muscle weakness, and infection with fever *prior* to quinidine administration, hypersensitivity reactions to the drug may be masked.

DRUG INTERACTIONS:

1. Caution should be used when quinidine and its analogs are administered concurrently with coumarin anticoagulants. This combination may reduce prothrombin levels and cause bleeding.
2. Quinidine, a weak base, may have its half-life prolonged in patients who are concurrently taking drugs that can alkalize the urine, such as thiazide diuretics, sodium bicarbonate, and carbonic anhydrase inhibitors. Quinidine and drugs which alkalize the urine should be used together cautiously.
3. Quinidine exhibits a distinct anticholinergic activity in the myocardial tissues. An additive vagolytic effect may be seen when quinidine and drugs having anticholinergic blocking activity are used together. Drugs having cholinergic activity may be antagonized by quinidine.
4. Quinidine and other antiarrhythmic agents may produce additive cardiac depressant effects when administered together.
5. Quinidine interaction with cardiac glycosides (digoxin): See WARNINGS.
6. Antacids may delay absorption of quinidine but appear unlikely to cause incomplete absorption.
7. Phenobarbital and phenytoin may reduce plasma $t_{1/2}$ of quinidine by 50%.
8. Quinidine may potentiate the neuromuscular blocking effect in ventilatory depression of patients receiving decamethonium, tubocurare, or succinylcholine.

ADVERSE REACTIONS: Symptoms of cinchonism (ringing in the ears, headache, disturbed vision) may appear in sensitive patients after a single dose of the drug.
Gastrointestinal: The most common side effects encountered with quinidine are referable to this system. Diarrhea frequently occurs, but it rarely necessitates withdrawal of the drug. Nausea, vomiting, and abdominal pain also occur. Some of these effects may be minimized by administering the drug with meals.
Cardiovascular: widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardias and fibrillation; paradoxical tachycardia, arterial embolism and hypotension.
Hematologic: acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis.
CNS: headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, photophobia, diplopia, night blindness, scotomata); optic neuritis.
Dermatologic: cutaneous flushing with intense pruritus.
Hypersensitivity reactions: angioedema, acute asthmatic episode, vascular collapse, respiratory arrest.

DOSAGE AND ADMINISTRATION: Dosage should be titrated to give the desired clinical effect, e.g., elimination of paroxysmal rhythm or reduction in premature contractions (See CLINICAL PHARMACOLOGY). This will often require prolonged ambulatory ECG monitoring, as hour-to-hour variability renders brief ECG recordings unreliable. When doses larger than 2.5 g/day are used, quinidine blood levels should be monitored, if possible, and serial ECGs should be followed (See WARNINGS and PRECAUTIONS).

For prevention of premature contractions and maintenance of normal sinus rhythm following spontaneous reversion or electrical conversion, the usual dosage is from 330 mg to 660 mg every eight hours, most patients requiring the higher dose.

In elderly patients, and in patients in the lower end of the normal weight range, plasma quinidine determinations should be considered. Dosage adjustments may be required.

OVERDOSAGE: Cardiotoxic effects of quinidine may be reversed in part by molar sodium lactate; the hypotension may be reversed by vasoconstrictors and by catecholamines (since the vasodilation is partly due to alpha-adrenergic blockade).

HOW SUPPLIED: N 0071-0850 (P-D 850) Duraquin (quinidine gluconate tablets) 330-mg tablets are supplied in bottles of 100 tablets.

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

Just published, this comprehensive work covers every aspect of exercise and its role in **Diagnosis, Treatment,** and **Prevention** of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

Why buy an ECG if you can't see high-frequency and low-amplitude signals like these?

You can get instruments with good high-frequency response. Or others that can pick up low amplitudes. But would you really trust a diagnosis if you couldn't trust your ECG to do it all?

With the Cambridge Model 3038/2 3-channel ECG, you get all the recording fidelity you need . . . because you get signals from all parts of the complex. Distortion-free. Sharply defined. Every time.

Recorder frequency response of more than 200 Hz allows the 3038/2 to respond to high-frequency, low-amplitude signals so small, other ECG's may miss them. A combination of low-friction heated stylus and powerful servo-motor produces tracings so precise, no notches are slurred . . . no vital data lost — even when changes in signal level are less than 10 microvolts (0.1 mm at standard sensitivity).

Of course, you may want more than a superior tracing. *That's why* we've designed-in a semi-automatic mode to give you extra control and flexibility when patients are uncooperative or nervous. *That's why* you're able to add a variety of lead programming options to meet your exact recording format requirements. *And that's why* it's so expandable, you can add heart-sound/pulse-wave recording, a computer phone terminal, a hum filter unit . . . or even buy a special "S" version for double-duty use as a mobile, stand-alone ECG or the heart of a modular stress test system.

Get it *all*, with the Cambridge Model 3038/2. For details, write or call: Cambridge Instrument Company, 73 Spring St., Ossining, N.Y. 10562 (914) 941-8100.

The search for the perfect pace shape has finall turned the corr

It should come as no surprise to you that a number of pacemakers have taken on some pretty strange configurations.

In the final analysis, though, there can be only one ultimate shape. An optimum design. Biocompatibility superior to all others.

Introducing our S 3000. It comes with a small connection that provides *an optimum lead exit angle* free of harsh bends. It is a connection that is an integral part of the total shape. Not an obvious afterthought.

The S 3000 has softly rounded, high radius edges and corners. That's important for a pacemaker. After all, sharp edges can be traumatic. And they can cause pocket erosion.

Actual Size.

The gently curving, rectangula shape of the S 3000, plus its very low density, minimizes rotation and the capstan effect. Which leads us to our point.

At Vitatron, the challenge to us pacemaker that is electronically and tec biocompatibly superior, too.

CLINICAL STUDIES

Arrhythmia in Hypertrophic Cardiomyopathy: Exercise and 48 Hour Ambulatory Electrocardiographic Assessment With and Without Beta Adrenergic Blocking Therapy

WILLIAM J. McKENNA, MD
SIVABAKIYAM CHETTY, MRCP, FCP (SA)
CELIA M. OAKLEY, MD, FRCP, FACC
JOHN F. GOODWIN, MD, FRCP, FACC

London, England

Submaximal treadmill exercise electrocardiography and 48 hour ambulatory electrocardiographic monitoring were performed in 30 patients with hypertrophic cardiomyopathy both with and without beta adrenergic blocking therapy. During ambulatory electrocardiographic monitoring 1 patient (3 percent) had no arrhythmia, 14 patients (46 percent) had supraventricular tachycardia or paroxysmal atrial fibrillation, 13 (43 percent) had multiform or paired ventricular extrasystoles and 8 (26 percent) had ventricular tachycardia. The frequency of these ventricular arrhythmias was almost identical with and without beta adrenergic blocking drugs (mean dose in "propranolol equivalents" 280 mg daily). With beta blocking therapy fewer patients had supraventricular tachycardia; however, the difference was not significant. During exercise testing 18 patients (60 percent) had ventricular extrasystoles and 3 patients (10 percent) had paired ventricular extrasystoles and the frequency was almost identical with and without beta adrenergic blocking therapy. No routine echocardiographic or hemodynamic measurement predicted the serious ventricular arrhythmias.

It is concluded that asymptomatic ventricular arrhythmia is a common occurrence in patients with hypertrophic cardiomyopathy and its frequency is not reduced with beta adrenergic blocking therapy. Because occult arrhythmia may be the cause of sudden death it is important to detect it in these patients so that an effort can be made to improve prognosis with specific antiarrhythmic treatment.

From the Division of Cardiovascular Disease (Clinical Cardiology), Department of Medicine, Royal Postgraduate Medical School, London, England. Manuscript received April 17, 1979; revised manuscript received July 16, 1979, accepted July 25, 1979.

Address for reprints: John F. Goodwin, MD, Department of Clinical Cardiology, Hammersmith Hospital, Du Cane Road, London W12 OHS, England.

The association of sudden death with asymmetric hypertrophy of the heart in young adults was first made by Teare[1] in 1958. Hypertrophic cardiomyopathy has since been well recognized[2] and sudden death found to be the most common mode of death.[3] In coronary artery disease sudden death has been linked to serious ventricular arrhythmias.[4] In hypertrophic cardiomyopathy no clinical or hemodynamic variable has yet been identified as a reliable predictor of sudden death.[5] Several antecedent mechanisms have been proposed: tachycardia induced by exercise or emotion associated with a decrease in stroke volume and blood pressure, an increase in left ventricular outflow tract obstruction and

in resistance to left ventricular filling, myocardial ischemia or atrial fibrillation.[6] After the postmortem description of atrioventricular (A-V) nodal fragmentation[7] and the electrophysiologic description of dual A-V nodal pathways[8] the possibility of accessory pathways allowing reentry or tachyarrhythmias has also been suggested.[9] Any of these mechanisms might precipitate ventricular fibrillation but the exact antecedent events remain unknown. This study was undertaken to assess the frequency and type of unsuspected arrhythmias and their relation to exercise and to assess the effect of therapy with beta adrenergic blocking drugs.

Methods

Electrocardiographic testing: Thirty consecutive unselected patients with clinical and angiographic hypertrophic cardiomyopathy performed submaximal treadmill exercise electrocardiography and underwent 48 hour outpatient ambulatory electrocardiographic monitoring both with and without beta adrenergic receptor blocking drugs. The exercise tests were performed on the sport engineering treadmill machine using an X,Y,Z orthogonal lead system. The ambulatory electrocardiographic monitoring was performed using the Oxford Medilog cassette recorder and recording instrument and a Reynold's high speed pathfinder electrocardiographic analyzer. All records were analyzed by a physician. The grading system of Ryan et al.[10] for ventricular arrhythmia was used: grade 0, no ventricular extrasystoles in 24 hours; grade 1, occasional ventricular extrasystoles but no more than 30 in any hour of monitoring; grade 2, more than 30 ventricular extrasystoles in any hour of monitoring; grade 3, multiform ventricular extrasystoles; grade 4a, couplets (two consecutive ventricular extrasystoles); grade 4b, ventricular tachycardia (three or more ventricular extrasystoles in succession).

Patients: Thirteen patients were women and 17 were men. The mean age was 48 years (range 21 to 71). The symptoms were not particularly severe in that 20 patients were classified in New York Heart Association[11] class I or II and only 10 in class III or IV. Twenty-five patients had sinus rhythm and five had established atrial fibrillation. Twelve patients complained of palpitations, and five of these had had at least one previous syncopal episode. The dose of beta blocking agent in propranolol equivalents ranged from 60 to 800 mg/day (mean 280 mg/day) per patient. This dose was determined by a resting heart rate of 50 to 60 beats/min, a maximal exercise heart rate of 100 to 110 beats/min and optimal relief of symptoms of angina, dyspnea and palpitations without undue side effects from the drug.

Cardiac catheterization: All patients underwent right and left heart catheterization and left ventricular angiography. Patients were considered to have obstruction if the intraventricular pressure gradient measured under basal conditions or with provocation (isoproterenol infusion, amyl nitrate inhalation or Valsalva maneuver) was 30 mm Hg or greater. Coronary arteriography was performed when coexistent coronary artery disease was considered possible; none of the four patients studied had significant disease. The original or a repeated cardiac catheterization was performed within 3 years before the study in all patients. No patient had had previous cardiac surgery.

Statistical significance was assessed using the unpaired *t* test, the chi square test or the Fisher Exact test.

Results

Ambulatory electrocardiographic monitoring: Twenty-eight of the 30 patients were studied both with and without beta blocking drugs. One patient could be studied only during beta blocking therapy because her chest pain became significantly worse when therapy was stopped; another patient could be studied only without beta blocking drugs because he had severe left ventricular failure. Table I summarizes the supraventricular arrhythmias detected during 48 hour ambulatory electrocardiographic monitoring.

Atrial extrasystoles were common and the overall frequency was identical with and without beta blocking therapy. Thirteen patients had frequent atrial extrasystoles (more than 30/hour) and seven had occasional atrial extrasystoles (30 or less/hour) without beta blocking therapy; 15 patients had frequent and 5 had occasional atrial extrasystoles with beta blocking therapy.

Fourteen patients had supraventricular tachycardia (including paroxysmal atrial fibrillation); the frequency of these atrial arrhythmias was reduced, but not significantly so, with beta blocking drugs. Without beta blocking therapy, 10 patients had supraventricular tachycardia; with it, 6 patients had supraventricular tachycardia.

TABLE I

Supraventricular Arrhythmias Detected During 48 Hour Ambulatory Electrocardiographic Monitoring With and Without Beta Adrenergic Blocking Drugs

	Without Beta Blocking Agents (24 patients*)		With Beta Blocking Agents (25 patients*)	
	no.	%	no.	%
Atrial extrasystoles				
None	4	16	5	20
≤30/hour	7	29	5	20
>30/hour	13	54	15	60
Supraventricular tachycardia	10	41	6	24

* Five patients with atrial fibrillation excluded.
no. and % = number and percent of patients, respectively.

TABLE II

Ventricular Arrhythmia Detected During 48 Hour Ambulatory Electrocardiographic Monitoring With and Without Beta Adrenergic Blocking Drugs

	Without Beta Blocking Agents (29 patients)		With Beta Blocking Agents (29 patients)	
Arrhythmia Grade*	no.	%	no.	%
0 (no VES)	4	14	7	28
1 (≤30 VES/hour)	6	21	5	17
2 (>30 VES/hour)	19	66	16	56
3 (multiform VES)	11	38	11	38

* Classification of Ryan et al.[10]
no. and % = number and percent of patients, respectively; VES = ventricular extrasystole; VT = ventricular tachycardia.

Table II summarizes the ventricular arrhythmias detected during 48 hour ambulatory electrocardiographic monitoring. Twenty-seven of the 30 patients had ventricular arrhythmias and the frequency was similar with and without beta blocking therapy. Without therapy 32 percent had more than 100 ventricular extrasystoles/24 hours, 66 percent had more than 30 ventricular extrasystoles/hour and 38 percent had multiform and 31 percent paired ventricular extrasystoles. With beta blocking therapy, 28 percent had more than 100 ventricular extrasystoles/24 hours, 56 percent had more than 30 ventricular extrasystoles/hour and 38 percent had multiform and 28 percent paired ventricular extrasystoles. Eight patients had ventricular tachycardia and the frequency was identical with and without beta blocking therapy.

Table III summarizes the clinical and ambulatory electrocardiographic findings in the patients with ventricular tachycardia. Three patients had a single episode of ventricular tachycardia only in the absence of beta blocking therapy and three patients had a single episode of ventricular tachycardia only with therapy. Patient 7 had six episodes of ventricular tachycardia without beta blocking therapy but could not be studied during therapy because he had left ventricular failure. He was subsequently admitted to the hospital for control of his arrhythmia but died suddenly. His medications were digoxin, diuretic drugs and disopyramide. Patient 8 had seven episodes of ventricular tachycardia without and eight episodes with therapy. He died suddenly at home while watching television. His medications were diuretic drugs and disopyramide. The frequency of ventricular extrasystoles in 24 hours was similar with and without beta blocking therapy in these eight patients and was significantly different from that in the remaining 22 patients who did not have ventricular tachycardia ($p = 0.05$). The incidence of paired or multiform ventricular extrasystoles was also significantly different: 75 percent in the group with ventricular tachycardia compared with 24 percent in the group with nonventricular tachycardia ($p = 0.05$). Neither the pulmonary capillary wedge pressure nor the presence of intraventricular obstruction was predictive of ventricular tachycardia. In fact, with beta blocking therapy 58 percent of patients without obstruction and 35 percent of those with obstruction had serious ventricular arrhythmia (grade 3, 4a and 4b); however, this difference was not statistically significant (Fig. 1). No patient had second or third degree A-V block or evidence of sinus node disease.

Exercise electrocardiography: Table IV summarizes the results of treadmill exercise electrocardiography. Twenty-eight patients performed submaximal treadmill exercise testing both with and without beta blocking therapy. The patients exercised until they became symptomatic and each patient performed an equivalent amount of exercise with and without therapy. Without therapy the mean resting heart rate was 78 beats/min (range 70 to 95 beats/min). At peak exercise the mean maximal heart rate was 150 beats/min (range 110 to 170 beats/min). Eighteen patients had ventricular extrasystoles and two of these patients had paired ventricular extrasystoles after peak exercise. With beta blocking drugs the mean resting heart rate was 56 beats/min (range 40 to 60). At peak exercise the mean maximal heart rate was 100 beats/min (range 90 to 125). Fifteen patients had ventricular extrasystoles and three of these patients had paired ventricular extrasystoles

Resting	70–95	40–60
Mean	78	56
Maximal	110–170	90–125
Mean	150	100
Arrhythmia (no.)		
<1 VES/min*	14	13
≥1 VES/min	4	2

* Two patients had coupled ventricular extrasystoles both with and without beta blocking agents and one patient had coupled ventricular extrasystoles only with beta blocking therapy.
no. = number of patients; VES = ventricular extrasystoles.

after exercise. No other arrhythmias were detected either with or without beta blocking therapy during exercise testing. There was no correlation between serious ventricular arrhythmia on ambulatory electrocardiographic monitoring and ventricular extrasystoles on exercise.

Discussion

Arrhythmia: Our results revealed asymptomatic arrhythmia to be frequent in hypertrophic cardiomyopathy. Ambulatory electrocardiographic monitoring showed that 50 percent of patients had multiform or paired ventricular extrasystoles or ventricular tachycardia and that 46 percent had supraventricular tachycardia that was not detected during exercise testing. Twenty-six percent of patients had ventricular tachycardia and two patients who had frequent ventricular tachycardia died suddenly within 6 months of completion of the study. Savage et al.[12] reported a similar high incidence rate of serious ventricular arrhythmia in hypertrophic cardiomyopathy. They also found that more of the arrhythmias were exposed with ambulatory electrocardiographic monitoring than with exercise testing.

Maron et al.[5] reviewed the cases of 26 patients with hypertrophic cardiomyopathy who had died suddenly and found that a distinctly abnormal electrocardiogram and the necropsy finding of moderately increased ventricular septal thickness (which has been shown to correlate with echocardiographic measurement of ventricular septal thickness) were the only characteristic features and that no specific clinical or hemodynamic feature was a reliable predictor of death. In our study the frequency of multiform or paired ventricular extrasystoles was associated with the finding of ventricular tachycardia, and the two patients who died both had frequent multiform and paired ventricular extrasystoles. No clinical, routine echocardiographic, electrocardiographic or hemodynamic feature, including family history, ventricular septal thickness and elevated left ventricular end-diastolic pressure, was a reliable predictor of serious ventricular arrhythmia.

Atrial fibrillation has long been regarded as an indicator of poor prognosis.[13] In our study 46 percent of the patients had supraventricular tachycardia or paroxysmal atrial fibrillation and 16 percent had established atrial fibrillation. These arrhythmias did not predict serious ventricular arrhythmia and, in turn, they were not predicted by any clinical, electrocardiographic or hemodynamic variable.

Mechanism of ventricular arrhythmias and sudden death: It is not surprising that the patients with hypertrophic cardiomyopathy who are in atrial fibrillation with grossly elevated filling pressures and low cardiac output should die suddenly of presumed ventricular fibrillation. However, it is unsettling that sudden death is not limited to those patients with advanced disease and may also occur in the asymptomatic patient.[5] Serious ventricular arrhythmias predispose the patient with hypertrophic cardiomyopathy to sudden death, but what is the antecedent mechanism?

After the description of A-V nodal fragmentation by James and Marshall,[7] Goodwin and Krikler[9] proposed rapid A-V transmission by way of an accessory pathway with rapid ventricular response and fibrillation as a possible mechanism of sudden death. In our series of 266 patients with hypertrophic cardiomyopathy, classic Wolff-Parkinson-White syndrome was seen in only three patients, and in this study none of the 30 patients had episodes of tachycardia or a QRS configuration suggesting preexcitation.

It is possible that ischemic arrhythmias are the mechanism of sudden death. Systolic compression of septal perforator vessels has been demonstrated angiographically in hypertrophic cardiomyopathy[14] and narrowing of small septal arteries has been shown at necropsy by James and Marshall.[7] Six of the eight patients with ventricular tachycardia had bradycardia (rate 48 to 60 beats/min) immediately before the epi-

sodes of ventricular tachycardia; the remaining two patients had a heart rate of 100 and 110 beats/min, respectively, before their episodes of ventricular tachycardia. The mechanism of ventricular tachycardia may not be the same in all patients but it is probably not related to ischemia.

Beta adrenergic blockade: Our results corroborate the findings of Ingham et al.[15] in 16 patients and show no significant alteration in the frequency of supraventricular or ventricular arrhythmia with beta adrenergic blocking therapy in hypertrophic cardiomyopathy. Ventricular tachycardia was preceded by tachycardia in only two patients and by bradycardia in six patients and no patient had ventricular tachycardia during exercise. It is therefore not surprising that treatment with beta adrenergic blocking drugs had no effect on the frequency of serious ventricular arrhythmia. Frank et al.[16] recently reported no deaths at 5 years among 22 patients treated with massive beta adrenergic blocking doses of propranolol and suggest that a daily dose of propranolol of less than 320 mg was rarely effective. One of our patients with ventricular tachycardia was taking 800 mg of propranolol, and three others had propranolol-equivalent doses of greater than 400 mg/day.

Alternative antiarrhythmic agents should therefore be sought for the treatment of ventricular arrhythmias and their efficacy tested in individual patients. Beta blocking drugs should principally be used for the control of established and paroxysmal atrial fibrillation and for alleviation of symptoms, especially angina pectoris.

To assess the reliability of the classic echocardiographic features in the heart with hypertrophic cardiomyopathy as criteria that differentiate it from normal heart and as predictors of outflow tract obstruction versus nonobstruction, 70 patients with clinical and angiographic evidence of hypertrophic cardiomyopathy were studied with M mode echocardiography. The diagnostic sensitivity and specificity of the classic features were assessed: ventricular septal thickness, 83 and 94 percent (sensitivity and specificity, respectively); ventricular septal amplitude of movement, 71 and 89 percent; ventricular septal thickness to left ventricular posterior wall ratio, 79 and 94 percent; left ventricular end-systolic dimension, 54 and 86 percent; septal-mitral valve distance at the onset of systole, 29 and 100 percent; systolic anterior motion of the mitral valve, 61 and 100 percent; and mid systolic closure of the aortic valve, 61 and 100 percent.

No single M mode echocardiographic feature was consistently abnormal in hypertrophic cardiomyopathy. In nonobstructive hypertrophic cardiomyopathy, ventricular septal thickness greater than or equal to 13 mm (sensitivity 68 percent and specificity 94 percent) and ventricular septal thickness to posterior wall ratio greater than or equal to 1.5 (sensitivity 82 percent and specificity 94 percent) were the individual features with the greatest diagnostic value from the norm. Patients with obstruction at rest and labile obstruction (gradient only on provocation) had echocardiographically identical features. Ventricular septal thickness greater than or equal to 13 mm plus systolic anterior motion of the mitral valve or mid systolic closure of the aortic valve were the features that in combination best differentiated obstructive (resting and labile) from nonobstructive hypertrophic cardiomyopathy (sensitivity 82 percent and specificity 68 percent) and the heart with obstructive hypertrophic cardiomyopathy from the normal heart (sensitivity 82 percent and specificity 100 percent).

For the past decade echocardiography has been widely used in the diagnosis of hypertrophic cardiomyopathy and various echocardiographic features have been described as characteristic of the disease: thickened ventricular septum,[1,2] inert ventricular septum,[3–5] abnormal ventricular septal thickness to left ventricular posterior wall ratio,[1–3,5–7] systolic anterior motion of the mitral valve,[8–12] decreased septal-mitral valve distance at the onset of systole,[13,14] small left ventricular cavity[7,15,16] and mid systolic closure of the aortic valve.[17–20]

Systolic anterior motion of the mitral valve was the first echocardiographic abnormality to be observed in hypertrophic cardiomyopathy, and subsequently this criterion was promoted for the prediction[8–12] and even the quantification[7,21] of outflow tract obstruction. Later, "asymmetric septal hypertrophy" was introduced as the pathognomonic echocardiographic counterpart of the essential morphologic abnormality in this disorder.[6,7] More recently the diagnostic value of both these

echocardiographic abnormalities has been called into question. Systolic anterior motion of the mitral valve has been found in patients with hypertrophic cardiomyopathy without obstruction[22–24] as well as in other conditions.[10,24–34] Asymmetric septal hypertrophy has been reported in normal children,[35] in athletes[36,37] and in patients with congenital and acquired heart disease.[16,24,25,27,30,34,35,38–43]

Although the classic echocardiographic features have been repeatedly described,[1–43] their specificity in the diagnosis of hypertrophic cardiomyopathy and their predictive value in the recognition of outflow tract obstruction remain uncertain. It is the purpose of this study to assess the reliability of the seven echocardiographic features as criteria that can be used to differentiate the heart with hypertrophic cardiomyopathy from the normal heart and to predict the presence of obstructive versus nonobstructive hypertrophic cardiomyopathy in a large series of patients.

Methods

Patients: Seventy patients with clinical and angiographic evidence of hypertrophic cardiomyopathy,[44] 42 of whom were male, and 28 female (age range 12 to 70 years, mean 44 years), were studied with M mode echocardiography. All the patients were studied within 6 months of cardiac catheterization. They were separated into three groups based on hemodynamic determination of left ventricular outflow tract obstruction: 27 patients had a left ventricular outflow tract pressure gradient at rest (resting obstruction), 21 patients had no left ventricular outflow tract gradient at rest, but showed a gradient on provocation (labile obstruction) and 22 patients had hypertrophic cardiomyopathy without obstruction either at rest or on provocation (nonobstruction).

Thirty-six normal subjects, 16 male and 20 female (age range 14 to 61 years, mean 32 years), were also studied; they included 16 members of the Hammersmith Hospital staff and 20 patients referred for evaluation of functional murmurs who did not show clinical, phonocardiographic or echocardiographic evidence of cardiac disease. Results from this group were regarded as the basis for comparison.

Echocardiography: Left ventricular, mitral valve leaflet, aortic root and left atrial echocardiograms were obtained by the standard methods[45] with the Ekoline 20 Ultrasonoscope using a 2.25 megahertz transducer with a repetition frequency of 1,000 pulses/s. The output was displayed on a Cambridge strip chart recorder with a simultaneous electrocardiogram. Studies were made with subjects in the supine or slight left lateral position with the transducer at the left sternal edge.

Seven classic echocardiographic features of hypertrophic cardiomyopathy were assessed (Fig. 1): (1) ventricular septal thickness at end diastole; (2) ventricular septal amplitude of movement; (3) ventricular septal thickness to left ventricular posterior wall ratio; (4) left ventricular end-systolic dimension; (5) septal-mitral valve distance at the onset of systole; (6) systolic anterior motion of the mitral valve; and (7) mid systolic closure of the aortic valve. Features 1 to 4 were assessed from the echocardiograms obtained just below the plane of the mitral valve, where the minor axis of the left ventricle was recorded. Features 5 and 6 were assessed from the echocardiograms obtained at the plane of the mitral valve tip where both anterior and posterior leaflets were recorded simultaneously. Feature 7 was assessed from the echocardiograms

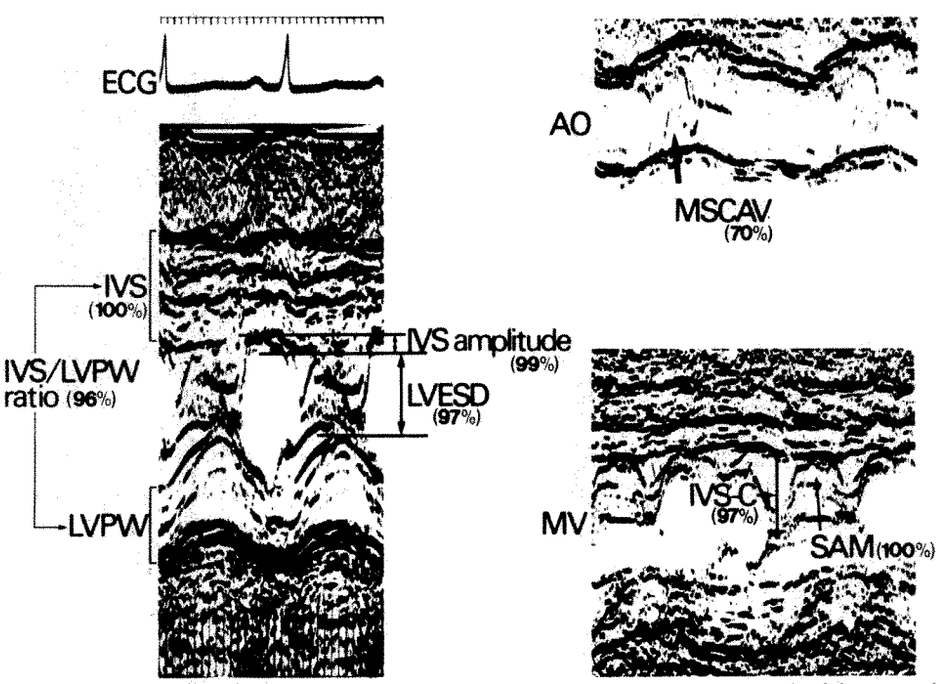

FIGURE 1. Seven classic features in hypertrophic cardiomyopathy. The numbers in parentheses under each of the seven features indicate the percent of the echocardiograms that were adequate for the assessment of the feature indicated. AO = aorta; ECG = electrocardiogram; IVS = interventricular septum; IVS-C = septal-mitral valve distance at the onset of systole; LVESD = left ventricular end-systolic dimension; LVPW = left ventricular posterior wall; MSCAV = mid systolic closure of the aortic valve; MV = mitral valve; SAM = systolic anterior motion of the mitral valve.

Data represent mean values (± standard deviation when indicated); figures in brackets represent 95 percent confidence limits of the median values; figures in parentheses indicate range of values. IVS = interventricular septum; IVS-C = septal-mitral valve distance at the onset of systole; LVESD = left ventricular end-systolic dimension; LVPW = left ventricular posterior wall; MSCAV = mid systolic closure of the aortic valve; SAM = systolic anterior motion of the mitral valve; Vcf = velocity of circumferential fiber shortening.

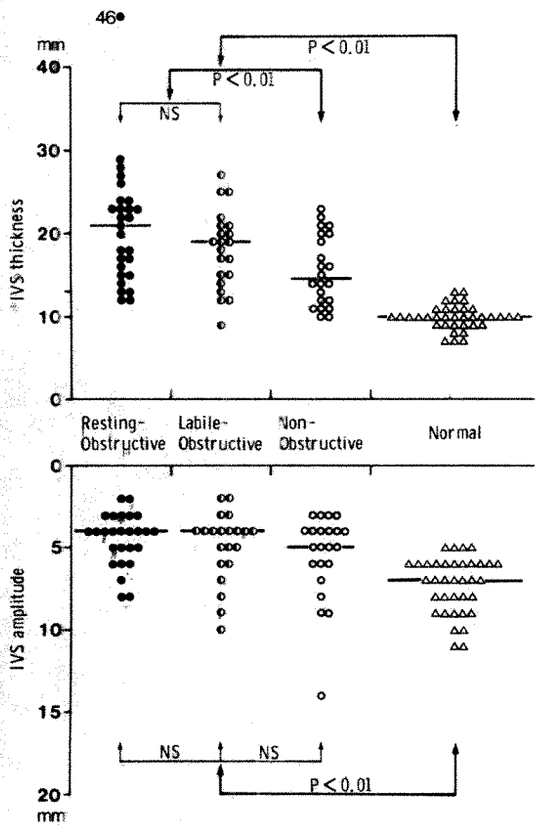

FIGURE 2. Interventricular septal (IVS) thickness and amplitude of motion in patients with resting, labile and nonobstructive hypertrophic cardiomyopathy and in normal subjects. NS = not significant; P = probability.

obtained at the plane of the aortic root and the left atrium where both anterior and posterior aortic cusps were visualized. The attainment of proper beam direction was carefully checked by scanning several times from the aortic root through the mitral valve to the plane where the minor axis of the left ventricle was obtained. The quality of the echocardiograms was adequate for the assessment of the first six features in more than 96 percent and for mid systolic closure of the aortic valve in 70 percent of the patients.

In addition, the following indexes of left ventricular function were assessed: left ventricular posterior wall excursion, and septal systolic thickening which was expressed as systolic thickness minus diastolic thickness divided by diastolic thickness ([S-D]/D), and calculated mean velocity of circumferential fiber shortening (Vcf).

Statistical analysis: Standard statistical analyses were performed. The difference between two proportions was tested using Fisher's Exact test. The two sample t test was used to test the difference between two means and the two-sample Wilcoxon test was used to differentiate between the two samples when the data were not normally distributed.

Results (Table I)

Ventricular septal thickness: The median ventricular septal thickness in all patients with hypertrophic cardiomyopathy was significantly different from that in normal subjects ($p < 0.01$) and the median ventricular septal thickness in patients with resting and labile obstructive cardiomyopathy was significantly greater than the value in those with nonobstructive hypertrophic cardiomyopathy ($p < 0.01$) (Fig. 2). The diagnostic sensitivity and specificity were 83 and 94 percent, respectively, when ventricular septal thickness of 13 mm or more was defined as abnormal (Table II).

TABLE II

Sensitivity (percent) and Specificity (percent) of Seven Classic Echocardiographic Features

	Differentiation of HCM From Normal State		Differentiation of Nonobstructive HCM From Normal State		Differentation of Resting and Labile Obstructive HCM From Nonobstructive HCM	
Echocardiographic Features	Sensitivity	Specificity	Sensitivity	Specificity	Sensitivity	Specificity

≥1.5	79	94	82	94	77	18
LVESD						
<25mm	54	86	46	86	61	50
IVS-C						
<20mm	29	100	14	100	37	86
<25mm	63	92	50	92	70	50
<27mm	78	89	64	89	85	36
SAM	61	100	27	100	77	73
MSCAV	61	100	21	100	77	79

HCM = hypertrophic cardiomyopathy; IVS = interventricular septum; IVS-C = septal mitral valve distances at the onset of systole; LVESD = left ventricular end systolic dimension; LVPW = left ventricular posterior wall; MSCAV = mid systolic closure of the aortic valve; SAM = systolic anterior motion of the mitral valve.

Ventricular septal amplitude of movement: The median ventricular septal amplitude of movement in all patients with hypertrophic cardiomyopathy was significantly less than that in normal subjects ($p < 0.01$), but there was no significant difference among the median values in patients with resting, labile or nonobstructive hypertrophic cardiomyopathy (Fig. 2). The diagnostic sensitivity and specificity were 71 and 89 percent, respectively, when ventricular septal amplitude of movement of 5 mm or less was defined as abnormal (Table II).

Ventricular septal thickness to left ventricular posterior wall ratio: In all patients with hypertrophic cardiomyopathy this ratio was significantly greater than that in normal subjects ($p < 0.01$) and there was no significant difference among the patients with resting, labile and nonobstructive hypertrophic cardiomyopathy (Fig. 3). The diagnostic sensitivity and specificity were 79 and 94 percent, respectively, when ventricular septal thickness to posterior wall ratio of 1.5 or greater was defined as abnormal (Table II).

Left ventricular end-systolic dimension: The mean value of this dimension in all patients with hypertrophic cardiomyopathy was significantly less than that in normal subjects ($p < 0.02$). There was no significant difference in this dimension between patients with obstructive and nonobstructive hypertrophic cardiomyopathy (Fig. 3). The diagnostic sensitivity and specificity were 54 and 86 percent, respectively, when a left ventricular end-systolic dimension of less than 25 mm was defined as abnormal (Table II).

Septal-mitral valve distance at the onset of systole: In comparison with that of the normal subjects, the mean septal-mitral valve distance at the onset of systole in all patients with hypertrophic cardiomyopathy was

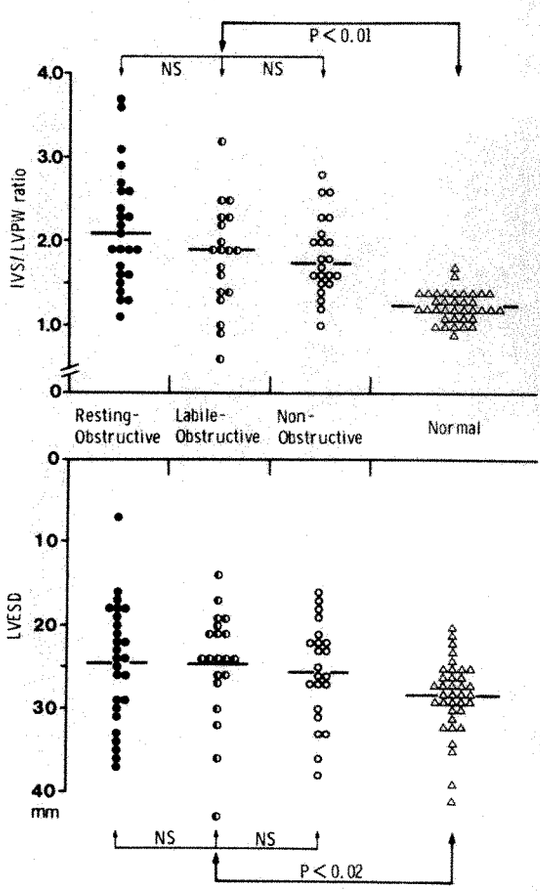

FIGURE 3. Interventricular septal (IVS) to left ventricular posterior wall (LVPW) ratio and left ventricular end-systolic dimension (LVESD) in patients with resting, labile and nonobstructive hypertrophic cardiomyopathy and in normal subjects.

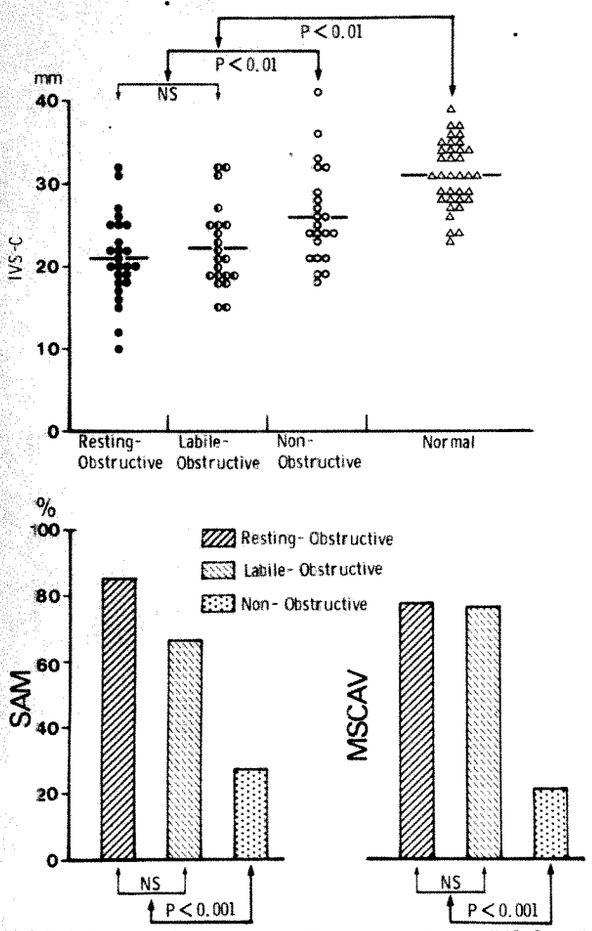

FIGURE 4. Interventricular septal-mitral valve distance (IVS-C) at the onset of systole, systolic anterior movement (SAM) of the mitral valve and mid systolic closure of the aortic valve (MSCAV) in patients with resting, labile and nonobstructive hypertrophic cardiomyopathy and in normal subjects.

significantly reduced ($p < 0.01$) and in patients with resting and labile obstruction it was significantly less than in those without obstruction ($p < 0.01$) (Fig. 4). The diagnostic sensitivity and specificity were 29 and 100 percent, respectively, when a systolic septal-mitral valve distance of less than 20 mm was defined as abnormal (Table II).

Systolic anterior motion of the mitral valve: No normal subject manifested systolic anterior motion of the mitral valve, but it was present in 61 percent of all patients with hypertrophic cardiomyopathy (Table II). Its presence did not differentiate the patients with resting obstruction from those with labile obstruction, but it did distinguish those two groups from the patients with nonobstructive cardiomyopathy ($p < 0.001$) (Fig. 4).

Mid systolic closure of the aortic valve: No normal subject had mid systolic closure of the aortic valve, but it was present in 61 percent of all patients with hypertrophic cardiomyopathy (Table II). Its presence did not differentiate the group with resting obstruction from that with labile obstruction, but did distinguish these two groups from the group with nonobstructive cardiomyopathy ($p < 0.001$) (Fig. 4).

Discussion

Ventricular septal thickness: A markedly thickened ventricular septum causing "functional obstruction" of the left ventricular outflow tract in the absence of aortic valve disease was first noted at operation by Lord Brock[46] in 1957. A year later Teare[47] described eight cases of sudden death in young adults with asymmetric hypertrophy of the heart. The predominant pathologic finding was a grossly hypertrophied ventricular septum. Menges et al.[48] in 1961 provided measurements of ventricular septal thickness and left ventricular posterior wall thickness in three necropsy cases and subsequently a larger number of cases was similarly reported.[49–51] A thickened ventricular septum had previously been noted echocardiographically,[52] but Abbasi et al.[1] were the first to provide specific measurements in eight patients.

Henry et al.[51] and recently Gilbert et al.[53] reported a significant difference in mean ventricular septal thickness between patients with obstructive versus nonobstructive hypertrophic cardiomyopathy (Table III). Gilbert et al. indicated that left ventricular outflow tract obstruction was more likely to be present with a thicker septum and a narrower septal-mitral valve distance. We found a difference between the median ventricular septal thickness in patients with obstruction (both resting and labile) and that in patients without obstruction ($p < 0.01$), and this association of a thickened ventricular septum with obstruction suggests that the septum itself may play a part in the obstruction simply by narrowing the outflow tract of the left ventricle.[54] Our results also showed that ventricular septal thickness in patients with hypertrophic cardiomyopathy was significantly greater than that in normal subjects ($p < 0.01$). However, 12 of 70 patients (17 percent) with hypertrophic cardiomyopathy had a ventricular septal thickness of less than 13 mm and 7 of these patients had no outflow tract obstruction. Also, 2 of 36 normal control subjects (5 percent) had a ventricular septal thickness equal to 13 mm.

Ventricular septal amplitude of movement: The ventricular septum in hypertrophic cardiomyopathy has been described as an adynamic and functionally immobile structure.[3–5] We found a significantly reduced ventricular septal amplitude of movement in hypertrophic cardiomyopathy ($p < 0.01$) with grossly decreased septal systolic thickening; however, 29 percent of the patients with hypertrophic cardiomyopathy had a ventricular septal amplitude of motion of 5 mm or more which is within the normal range.

Hagen et al.[55] demonstrated echocardiographically a pivot point of the ventricular septum; the superior segment of the septum moves anteriorly during systole, and below the pivot point the lower two thirds of the septum moves posteriorly during systole. They stressed that it is important to evaluate ventricular septal motion with a beam direction below the plane of the mitral valve and since the work of Rossen et al.,[4] it has been

AS = aortic stenosis; HT = hypertension; IVS = interventricular septum; LVH = left ventricular hypertrophy; LVPW = left ventricular posterior wall.

Data represent mean values ± standard error of the mean; figures in parentheses indicate values for the three groups of patients with cardiomyopathy.

conventional in hypertrophic cardiomyopathy to measure septal motion just below the plane of the mitral valve, where the minor axis of the left ventricle is recorded. Although measurement of the ventricular septal amplitude of movement just below the plane of the mitral valve is of diagnostic value, the interpretation that the whole (or entire) septum is an immobile structure may not be correct.[56]

Ventricular septal thickness to left ventricular posterior wall ratio: This feature was first described echocardiographically by Abbasi et al.[1] in 1972 (Table III), and a year later Henry et al.[6] claimed that a ventricular septal thickness to posterior wall ratio greater than or equal to 1.3, which they termed "asymmetric septal hypertrophy," was a pathognomonic echocardiographic abnormality of hypertrophic cardiomyopathy. Subsequently, however, "asymmetric septal hypertrophy" has been reported in normal infants and young children without heart disease[35] and in patients with congenital heart disease,[24,35,38,39,40] myocarditis,[35] hyperlipidemia (type II),[35] coronary artery disease,[41,42] primary pulmonary hypertension,[30] systemic hypertention,[16,25,43] and other forms of valvular and subvalvular left ventricular outflow tract obstruction[16,26,27,34] as well as in normal athletes, including basketball players[36] and weight-lifters.[37] Obviously "asymmetric septal hypertrophy" defined as a ventricular septal thickness to posterior wall ratio of 1.3 or more is not specific for hypertrophic cardiomyopathy. Although 91 percent of our patients with hypertrophic cardiomyopathy had "asymmetric septal hypertrophy" as defined by this ratio, so did 44 percent of our normal subjects. In an attempt to improve the specificity of this "diagnostic" feature, several authors[2,14,54] have suggested a ratio of 1.5 or greater. Reanalyzing our data utilizing a ratio greater than or equal to 1.5 as the diagnostic cutoff point, we found a sensitivity of 79 percent and specificity of 94 percent (Table II).

Although early reports[2,6] on small numbers of patients suggested that a ratio of 1.3 or more was diagnostic, a review of published data suggests that this criterion is not specific enough to differentiate hypertrophic cardiomyopathy from other forms of secondary left ventricular hypertrophy. Gibson et al.[16] recently published echocardiographic measurements in 27 patients with hypertension and 21 patients with aortic stenosis whose ventricular septal thickness to posterior wall ratio was 1.4 ± 0.5 and 1.3 ± 0.4, respectively (Table III); our unpublished data in 35 patients support their findings.

Left ventricular end-systolic dimension: A small left ventricular end-systolic chamber size was reported in several angiographic studies[44,58,59] and Tajik and Giuliani[3] first made the echocardiographic observation. Recently, Sanderson et al.[15] and then Gibson et al.[16] demonstrated reduced mean left ventricular end-systolic dimension in patients with hypertrophic cardiomyopathy in comparison with normal control subjects. Our results are similar and show a reduced mean left ventricular end-systolic dimension in hypertrophic

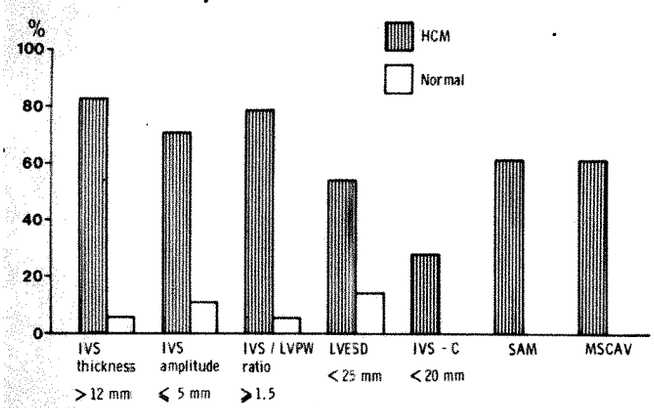

FIGURE 5. Sensitivity of each abnormal feature in 70 patients with hypertrophic cardiomyopathy (HCM) and in 36 normal subjects. Abbreviations as in Figures 1 through 4.

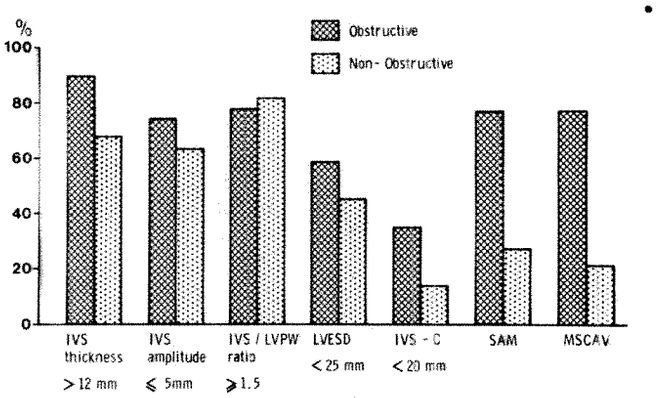

FIGURE 6. Sensitivity of each abnormal feature in 48 patients with obstructive and 22 patients with nonobstructive hypertrophic cardiomyopathy. Abbreviations as in Figures 1 through 4.

cardiomyopathy; however, the low sensitivity (54 percent) and specificity (86 percent) render this echocardiographic feature of little diagnostic value.

Septal-mitral valve distance at the onset of systole: Henry et al.[13] considered the narrowing of the left ventricular outflow tract at the onset of systole one of the factors responsible for the development of outflow tract obstruction, and in their series of 100 patients with hypertrophic cardiomyopathy only 6 percent of the patients without obstruction had a septal-mitral valve distance of less than 20 mm compared with 66 percent of patients with resting obstruction. They excluded patients with labile obstruction from their analysis. We found a statistically significant mean difference between patients with and without obstruction and between all patients with hypertrophic cardiomyopathy and normal subjects. However, only 29 percent of all patients with hypertrophic cardiomyopathy had a septal-mitral valve distance of less than 20 mm at the onset of systole. Maximal sensitivity (78 percent) and specificity (89 percent) for the differentiation of all patients with hypertrophic cardiomyopathy from normal subjects were obtained with less than 27 mm as the cutoff point. Maximal sensitivity (70 percent) and specificity (50 percent) for the differentiation of obstructive from nonobstructive hypertrophic cardiomyopathy were obtained with less than 25 mm as the cutoff point (Table II).

Systolic anterior motion of the mitral valve: This abnormality, reported by Shah et al.[8] as a typical feature of hypertrophic obstructive cardiomyopathy, has since been found in nonobstructive hypertrophic cardiomyopathy[22–24] and in other conditions. Adequate documentation with unequivocal complete systolic anterior motion was found in one patient with systemic hypertension[25] who might have had coexistent hypertrophic cardiomyopathy, in one patient with fixed subaortic stenosis,[26] in one patient with aortic and mitral stenosis[27] and in a patient with myeloid metaplasia who had been treated with noradrenaline.[28] Adequately documented incomplete systolic anterior motion of the mitral valve has been shown in patients with aortic valve disease,[29] primary pulmonary hypertension,[30] left ventricular aneurysm[31] and pericardial effusion.[32] Systolic anterior motion of the mitral valve has also been reported in right ventricular volume overload,[33,34] aortic valve disease[24,34] and mitral valve disease,[10,34] although unequivocal documentation was not provided.

Systolic anterior motion of the mitral valve was found in 77 percent of our patients with both resting and labile obstructive hypertrophic cardiomyopathy and in only 27 percent of our patients with nonobstructive hypertrophic cardiomyopathy. The difference is statistically significant ($p < 0.001$). In the six patients without obstruction systolic anterior motion of the mitral valve was incomplete.

Mid systolic closure of the aortic valve: This abnormality was described by many authors in obstructive hypertrophic cardiomyopathy,[17,18–20,45,60] but it has not been described in the nonobstructive form of the disease. Abnormalities of aortic valve motion and early systolic closure of the aortic valve were also described in discrete subaortic stenosis[18,19,61,62] and in ruptured aneurysm of the right coronary sinus of Valsalva;[18] however, in these cases there were characteristic features that allowed differentiation from the mid systolic closure of the aortic valve seen in hypertrophic cardiomyopathy.[18,19] Also, Feigenbaum[63] mentioned a patient with mitral regurgitation and a patient with ventricular septal defect who showed mid systolic closure of the aortic valve. However, full clinical and echocardiographic details are not available. More recently, Chahine et al.[20] studied 15 patients with hypertrophic cardiomyopathy and suggested that mid systolic closure of the aortic valve is useful in differentiating hypertrophic cardiomyopathy with true obstruction from the pseudo-obstruction secondary to catheter entrapment and cavity obliteration.

The precise mechanism of mid systolic closure of the aortic valve in hypertrophic cardiomyopathy is not well known, but it has been postulated that it is due to the suction effect (Venturi effect) of a high velocity bloodstream[64–66] in the first half of systole followed by a decrease in flow velocity in the second half.[67,68] This hypothesis fits our experience with intracardiac phono-

cardiography, which shows a mid systolic ejection murmur recorded from the left ventricular cavity.[69]

Mid systolic closure of the aortic valve was recorded in 78 percent of our patients with resting obstruction, in 76 percent of those with labile obstruction and in 21 percent of the patients with nonobstructive hypertrophic cardiomyopathy. These results are consistent with the elegant work of Martin et al.,[70] which showed no difference in the blood flow profile between patients with resting and those with labile obstruction. In predicting obstruction versus nonobstruction, the presence of mid systolic closure of the aortic valve had a 77 percent sensitivity and 79 percent specificity and is clearly useful in predicting the obstructive form of the disease but is not pathognomonic of it.

Clinical implications: No single echocardiographic feature was present in more than 83 percent of our patients with hypertrophic cardiomyopathy (Fig. 5). The two features that had high diagnostic specificity—systolic anterior motion of the mitral valve and mid systolic closure of the aortic valve—both occur in other conditions and were present in only 61 percent of our patients. It is therefore clear that no single M mode echocardiographic feature is diagnostic of hypertrophic cardiomyopathy.

In nonobstructive hypertrophic cardiomyopathy a ventricular septal thickness of 13 mm or greater and a ventricular septal thickness to left ventricular posterior wall ratio greater than or equal to 1.5 had the greatest specificity and sensitivity in differentiating the condition from the normal state (Table II). Two normal subjects (5 percent) would have been assigned an incorrect diagnosis with these criteria. This finding demonstrates the limitation of M mode echocardiography in distinguishing patients with this type of cardiomyopathy from normal subjects; moreover, published data indicate that ventricular septal thickness and the ventricular septal thickness to left ventricular posterior wall ratio would not differentiate nonobstructive hypertrophic cardiomyopathy from other forms of secondary left ventricular hypertrophy that are also characterized by septal hypertrophy.

Resting and labile obstructive hypertrophic cardiomyopathy are echocardiographically identical. A stepwise discriminant analysis showed that, in combination, ventricular septal thickness greater than or equal to 13 mm plus systolic anterior motion of the mitral valve or mid systolic closure of the aortic valve best differentiated obstructive from nonobstructive hypertrophic cardiomyopathy (sensitivity 82 percent and specificity 68 percent) (Fig. 6). This combination of features also best differentiated obstructive hypertrophic cardiomyopathy from the normal state (sensitivity 82 percent and specificity 100 percent).

Left Ventricular Relaxation and Filling Pattern in Different Forms of Left Ventricular Hypertrophy: An Echocardiographic Study

PETER HANRATH, MD
DETLEF G. MATHEY, MD
RALF SIEGERT, MD
WALTER BLEIFELD, MD, FACC

Hamburg, West Germany

To study left ventricular relaxation and filling in different forms of left ventricular hypertrophy, echocardiograms of the left ventricle in 24 patients with hypertrophic obstructive cardiomyopathy and in 24 patients with chronic left ventricular pressure overload (due to aortic stenosis in 6 and to severe arterial hypertension in 18) were analyzed by computer and compared with those of 28 normal subjects. The relaxation time index (minimal left ventricular dimension to mitral valve opening) was 13 ± 15 ms in normal subjects. This index was prolonged in patients with cardiomyopathy (93 ± 37 ms) and overload (66 ± 31 ms). During the interval from minimal left ventricular dimension to mitral valve opening both groups with left ventricular hypertrophy showed a marked increase in left ventricular dimension of 4.0 ± 2.2 mm and 3.0 ± 1.8 mm, respectively, which was significantly greater ($p < 0.001$) than in normal subjects (0.6 ± 0.5 mm). This was probably a result of an abnormal change in left ventricular shape during isovolumic relaxation.

The rapid filling phase and the increase in dimension during this period were significantly reduced in hypertrophic obstructive cardiomyopathy and chronic pressure overload. In contrast to findings in the patients with cardiomyopathy, in those with pressure overload the reduced increase in left ventricular dimension during the rapid diastolic filling period was compensated for by a greater dimensional increase due to atrial contraction, resulting in a normal end-diastolic dimension. These data indicate that significant prolongation of isovolumic relaxation is seen in different forms of left ventricular hypertrophy and is often associated with an abnormal diastolic filling pattern.

Recent echocardiographic and angiographic studies[1-3] have shown that hypertrophic obstructive cardiomyopathy is often associated with abnormal left ventricular relaxation and an abnormal diastolic filling pattern. In this study we examined whether these abnormalities are only typical for this special type of left ventricular hypertrophy or whether they can be found in other forms of left ventricular hypertrophy as well. Therefore, the time intervals and dimensional changes during left ventricular relaxation and filling were studied in normal subjects, in patients with hypertrophic obstructive cardiomyopathy and in patients with left ventricular hypertrophy due to chronic pressure overload.

Methods

Patients

Seventy-six subjects were studied and classified into three groups.

Normal subjects: This group consisted of 28 persons without evidence of heart disease; all had normal sinus rhythm. Thirteen were female and 15 male, with an age range of 17 to 46 years (mean 28).

From the Division of Cardiology, Department of Medicine II, University Hospital, Hamburg-Eppendorf, West Germany. This study was supported in part by Research Grant MMT02 from the Gesellschaft für Strahlen- und Umweltforschung MBH, Munich, West Germany. Manuscript received March 5, 1979; revised manuscript received and accepted July 25, 1979.

Address for reprints: Peter Hanrath, MD, Division of Cardiology, University Hospital, Martinistrasse 52, 2000 Hamburg 20, West Germany.

Hypertrophic obstructive cardiomyopathy: This group consisted of 24 patients, 15 female and 9 male (age range 19 to 67 years, mean 36). All but two had normal sinus rhythm. In all cases the diagnosis of hypertrophic obstructive cardiomyopathy was based on the typical echocardiographic features and in 21 patients it was confirmed with left heart catheterization. At the time of study, no patient was receiving beta adrenergic blocking agents or calcium antagonists; these drugs were discontinued at least 8 days before the echocardiographic study.

Chronic pressure overload: The third group consisted of 24 patients with chronic left ventricular pressure overload due to either aortic stenosis proved at left heart catheterization (6 patients) or to severe arterial hypertension (18 patients). Ten patients were female and 14 male, with an age range of 36 to 69 years (mean 53). At the time of study, the hypertensive patients were receiving diuretic or antihypertensive drugs (excluding beta blocking agents), and none received digitalis.

Echocardiographic Studies

Echocardiograms were obtained with a Picker Echoview C 80 ultrasonoscope using a 1.25 cm diameter, 2.25 megahertz transducer with a pulse repetition rate of 1,000 cycles/s. The recordings were made with a multichannel Honeywell 1856 strip-chart recorder at a paper speed of 50 mm/s along with an electrocardiogram. Studies were made with the patient in the left lateral position. Left ventricular echocardiograms were recorded at the level of the free edges of the mitral valve leaflets.

Computer analysis: Only those recordings were considered adequate for further computer analysis in which septal and posterior wall echoes and the time point (D) of mitral leaflet separation could clearly be identified for at least three entire cardiac cycles. The echocardiograms were then digitized with a handcontrolled crosswire cursor (Graph-Pen, Science Accessories Corporation, Southport, Connecticut) according to a computerized method. The details of this method are described elsewhere.[4]

In brief, the echocardiogram to be studied was calibrated with points defining a time interval of 500 ms, 1 cm depth and two successive R wave peaks in the electrocardiogram enclosing the cardiac cycle to be analyzed. Then the septal and posterior wall endocardium and epicardium as well as the time point of mitral valve opening were digitized. These data were processed by a computer (Mulby 3, Sperry Univac®, Aachen, West Germany) and analyzed with the help of a video screen and a keyboard. The following time and dimensional measurements were made (Fig. 1).

Measurements of time intervals: Time intervals were referred to the peak of the R wave of the first QRS complex as zero reference point. With respect to this reference point, the occurrence of the time points of the different left ventricular dimensions within the cardiac cycle could be exactly determined. Time intervals of particular interest for this study were the time point of mitral valve opening and the left ventricular filling period (cycle length minus time point of mitral valve opening). The time point of end-systole was defined as minimal left ventricular dimension (D), where its normalized first differential dD/dt × D was zero.

Measurements of left ventricular dimensions: End-systolic and end-diastolic left ventricular dimensions, percent shortening of the minor axis of the left ventricle, peak endocardial circumferential fiber shortening ($V_{CF\ max}$) and lengthening velocity, and the wall thickness of the interventricular septum and posterior wall at end-diastole were measured. The diastolic left ventricular dimension-time curve, which is divided into four phases (isovolumic relaxation, rapid filling, slow filling and filling due to atrial contraction), was analyzed by a method similar to that first described by Decoodt et al.[5] (Fig. 1).

An approximative measurement of the isovolumic relaxation period was obtained from the time difference between the time points of end-systolic dimension and mitral valve opening.[6–9] This interval is referred to as relaxation time index. After mitral valve opening, the rapid filling phase begins. Its end was defined as the point where the normalized lengthening rate had decreased to 50 percent of its peak value.[5] Similarly, the end of the slow filling period was determined as the point where the last lengthening peak due to atrial contraction reached half of its maximum. The increase in dimension due to atrial contraction was terminated with the peak of the next R wave.

In those cases in which a clearly separate peak of the normalized lengthening rate due to atrial contraction was seen, the slow filling period and filling due to atrial contraction were separately analyzed. This breakpoint determination enabled a calculation of the absolute time periods as well as of dimensional changes during each of these different phases (Fig. 1). Furthermore, these absolute time and dimensional values were related to the total left ventricular filling time (t LVF) and the total left ventricular diameter increase during this period and expressed in percent according to the following formulas:

$$t\,RF(\%) = \frac{ERF - MO}{t\,LVF} \times 100$$

$$t\,SF(\%) = \frac{ESF - ERF}{t\,LVF} \times 100$$

$$t\,AC(\%) = \frac{EAC - ESF}{t\,LVF} \times 100$$

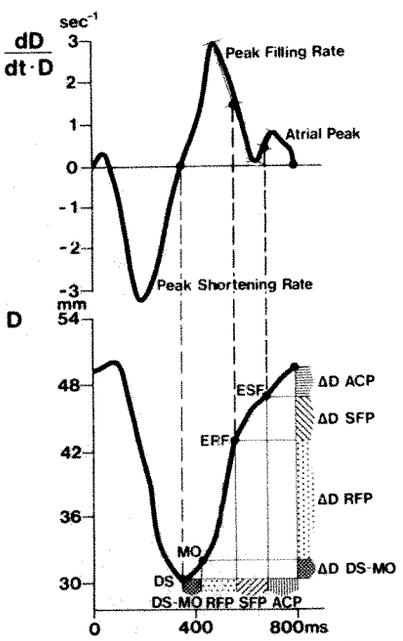

FIGURE 1. Dimension-time curve and its first normalized derivative for analysis of the different phases of left ventricular filling. ACP = filling phase due to atrial contraction; D = dimension; DS = end-systolic dimension; ERF = end point of the rapid filling phase; ESF = end point of the slow filling phase; MO = mitral valve opening; RFP = rapid filling phase; SFP = slow filling phase; t = time.

$$\Delta D\ RF(\%) = \frac{\Delta D\ (ERF - MO)}{\Delta D\ (EAC - MO)} \times 100$$

$$\Delta D\ SF(\%) = \frac{\Delta D\ (ESF - ERF)}{\Delta D\ (EAC - MO)} \times 100$$

$$\Delta D\ AC(\%) = \frac{\Delta D\ (EAC - ESF)}{\Delta D\ (EAC - MO)} \times 100,$$

where t = total, ERF = end point of the rapid filling phase, MO = mitral valve opening, LVF = left ventricular filling, ESF = end point of the slow filling phase, EAC = end point of the filling phase due to atrial contraction, and D = dimension.

The data were analyzed statistically using Student's *t* test.

Results

Normal Subjects

A representative example of a normal left ventricular dimension-time curve in an individual subject is given in Figure 2. For the whole group of 28 normal subjects, mean left ventricular cavity dimension at end-systole and end-diastole was 30.3 ± 4.5 (± 1 standard deviation) and 48.5 ± 5.3 mm, respectively, yielding a fractional shortening of the cavity dimension of 38 ± 5 percent. End-diastolic septal and posterior wall thickness was 9.5 ± 1.9 and 8.2 ± 1.4 mm, respectively. The sum of the end-diastolic wall thickness of the interventricular septum and the left ventricular posterior wall was 17.7 ± 2.4 mm. Mean heart rate was 72 ± 13 min^{-1} (Fig. 3).

The time interval between end-systolic left ventricular dimension and mitral valve opening was 13 ± 15 ms (range −29 to +35 ms). During this period a mean dimensional increase of 0.6 ± 0.5 mm was observed (Fig. 4).

After mitral valve opening, left ventricular dimension increased by 10.7 ± 2.2 mm during the rapid filling phase, which had a duration of 111 ± 32 ms (Fig. 5). In 17 of the 28 normal subjects the dimension-time curve could be further separated into a slow filling phase and a filling phase due to atrial contraction. The duration of these two phases was 264 ± 156 ms and 115 ± 44 ms, respectively. The absolute dimension increase during these periods was 4.1 ± 1.9 and 2.8 ± 1.8 mm, respectively. Duration and change in dimension expressed as percent of the total diastolic filling time and dimensional increase, respectively, were as follows (Fig. 5 and 6): rapid filling time, 27 ± 13 percent; slow filling time, 52 ± 16 percent; time of filling due to atrial contraction, 28 ± 18 percent; dimensional increase during rapid filling, 62 ± 10 percent; dimensional increase during slow filling, 22 ± 9 percent, dimensional increase during atrial contraction, 16 ± 10 percent.

Hypertrophic Obstructive Cardiomyopathy

Mean cavity dimensions at end-systole and end-diastole were 24.0 ± 5.0 and 42.7 ± 5.9 mm, respectively. Both dimensions were significantly smaller than those in normal subjects ($p < 0.001$). Thus, the fractional shortening of the left ventricular minor axis was greater (44 ± 7 percent, $p < 0.001$) than that of normal subjects. Heart rate was not different from the normal rate (71 ± 14 min^{-1}). Septal and posterior wall thickness at end-diastole was increased compared with normal values (21.9 ± 4.6 and 11.8 ± 2.3 mm, respectively; $p < 0.001$). The sum of the end-diastolic septal and pos-

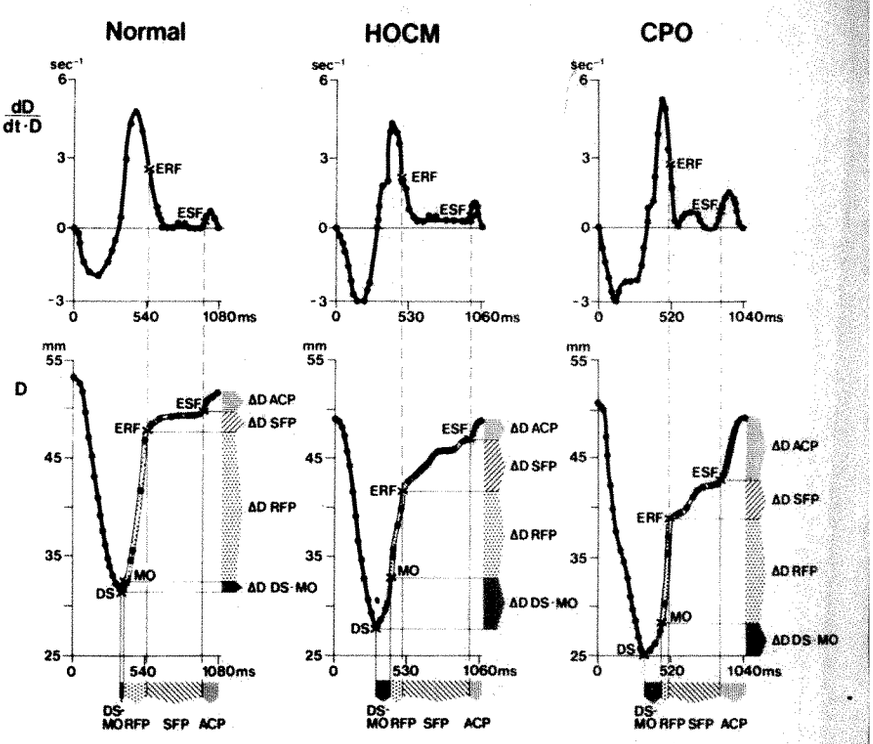

FIGURE 2. Computer output of the echograms of the left ventricular cavity of a normal subject (normal), a patient with hypertrophic obstructive cardiomyopathy (HOCM) and a patient with chronic left ventricular pressure overload (CPO). The normalized rate of left ventricular dimensional change is shown in the **upper panel.** In the patients with cardiomyopathy and pressure overload mitral valve opening (MO) with regard to minimal (end-systolic) left ventricular dimension (DS) is delayed and accompanied by an abnormal dimensional increase during this time interval. Furthermore, the time interval and the dimensional increase during the rapid filling phase (RFP) are reduced in both patients and followed by a large dimensional increase during atrial contraction in the patient with pressure overload. Unidentified abbreviations as in Figure 1.

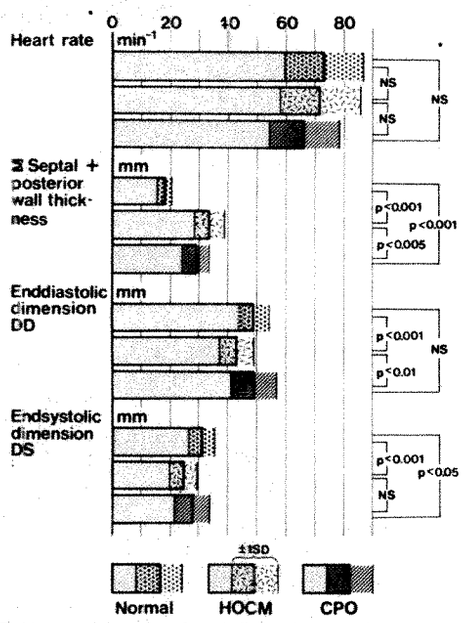

FIGURE 3. Heart rate, sum of end-diastolic septal and posterior wall thickness and end-diastolic (DD) and end-systolic (DS) left ventricular dimension are shown in normal subjects, patients with hypertrophic obstructive cardiomyopathy (HOCM) and chronic pressure overload (CPO) (mean value ± 1 standard deviation [SD]). NS = not significant; p = probability.

terior wall thickness was increased to 33.5 ± 5.1 mm ($p < 0.001$) (Fig. 3). The time interval from minimal left ventricular dimension to mitral valve opening (93 ± 37 ms) was significantly prolonged compared with the norm ($p < 0.001$). During this time period, left ventricular dimension increased by 4.0 ± 2.2 ($p < 0.001$) (Fig. 4).

The rapid filling period was reduced in absolute (78 ± 45 ms; $p < 0.005$) and relative (19 ± 11 percent; p

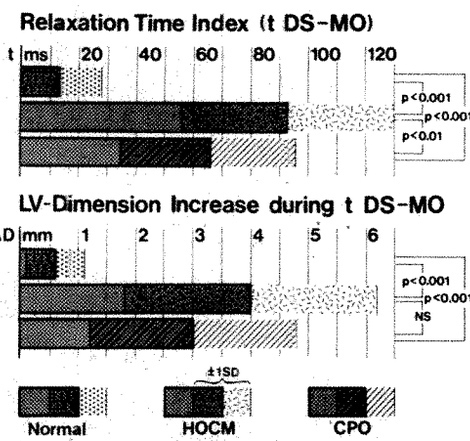

FIGURE 4. Relaxation time index (time interval from minimal left ventricular dimension to mitral valve opening) (tDS-MO) and left ventricular (LV) dimensional increase (ΔD) during this time interval in normal subjects, patients with hypertrophic obstructive cardiomyopathy (HOCM) and those with chronic left ventricular pressure overload (CPO) (mean value ± 1 standard deviation). Unidentified abbreviations as in Figures 1 and 3.

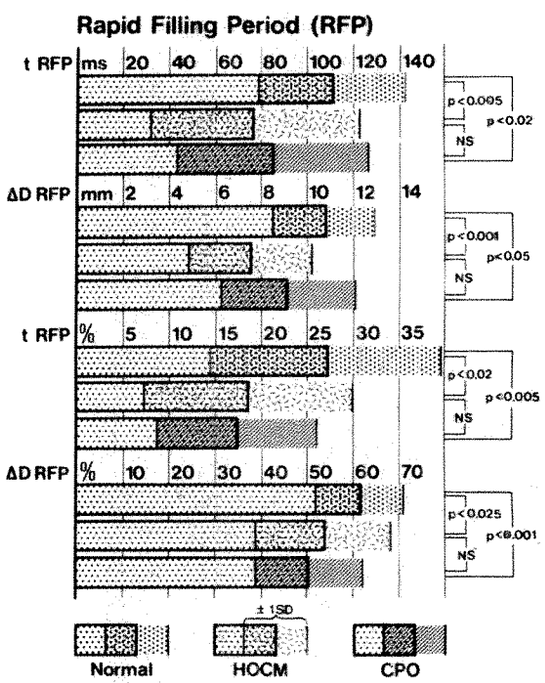

FIGURE 5. Time interval of the rapid filling period (RFP) in absolute (t RFP [ms]) and relative (t RFP [%]) terms and left ventricular dimensional increase during this time interval in absolute (ΔD RFP [mm]) and relative (Δ RFP [%]) terms (mean value ± 1 standard deviation). Unidentified abbreviations as in Figures 1 and 3.

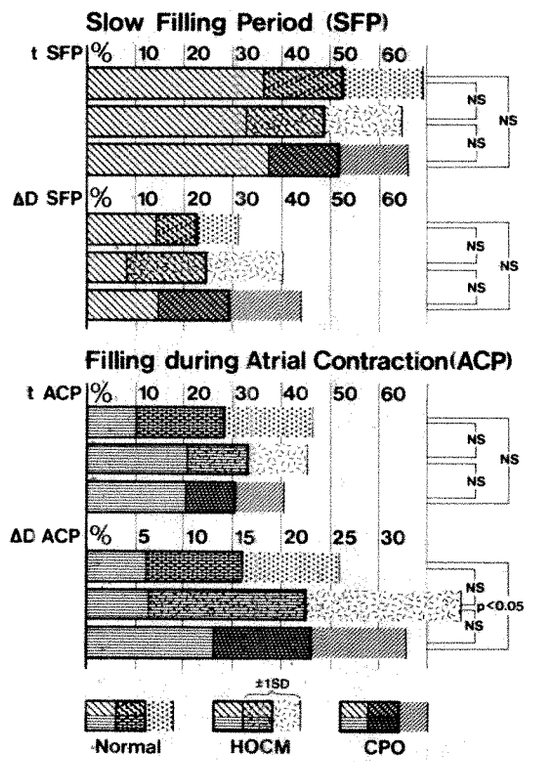

FIGURE 6. Time interval of the slow filling period (t SFP [%]) and filling due to atrial contraction (t ACP [%]) as well as left ventricular dimensional increase during these time periods (ΔD SFP [%] and ΔD ACP [%]) (mean value ± 1 standard deviation). Unidentified abbreviations as in Figures 1 and 3.

<0.02) terms compared with that in normal subjects. The absolute dimensional increase during the rapid filling period was 7.6 ± 2.7 mm (p <0.001); the relative dimensional increase with respect to the dimensional increase during left ventricular filling was 54 ± 15 percent (p <0.025) (Fig. 5). Concerning the slow filling phase and the filling behavior during atrial contraction, there was no significant difference in absolute and relative terms compared with that in normal subjects (Fig. 6). A typical dimension-time curve of a patient with hypertrophic obstructive cardiomyopathy is shown in Figure 2.

Left Ventricular Chronic Pressure Overload

Mean end-diastolic and end-systolic left ventricular dimension in these patients was 48.5 ± 7.9 and 26.9 ± 6.1 mm, respectively. The end-diastolic dimension was not different from the norm, but was significantly greater than it was in patients with hypertrophic obstructive cardiomyopathy (p <0.01). The end-systolic dimension was not different from that in patients with hypertrophic cardiomyopathy, but was significantly reduced in comparison with the control group (p <0.05). Fractional shortening of the left ventricular minor axis was 44 ± 8 percent and was significantly greater than that in normal subjects (p <0.005). Heart rate (66 ± 11 min^{-1}) was not different from that of normal subjects or patients with hypertrophic obstructive cardiomyopathy. Septal (16.6 ± 3.5 mm) and posterior (12.5 ± 2.6 mm) wall thickness was significantly greater compared with that of normal subjects (p <0.001). The septal wall thickness in patients with chronic pressure overload was smaller than that in hypertrophic cardiomyopathy (p <0.001). The sum of septal and posterior wall thickness (29.1 ± 48 mm) was greater than that in normal subjects (p <0.001), but smaller than that in hypertrophic obstructive cardiomyopathy. (p <0.005) (Fig. 3).

The mean interval from minimal left ventricular dimension to mitral valve opening in patients with chronic left ventricular pressure overload was 66 ± 31 ms and was significantly prolonged compared with that in normal subjects (p <0.001), but shorter than that in patients with hypertrophic cardiomyopathy (p <0.01). During this interval, left ventricular dimension increased significantly by 3.0 ± 1.8 mm (p <0.001 compared with that of normal subjects) (Fig. 4).

The rapid filling period in patients with chronic pressure overload was decreased in absolute (85 ± 42 ms) and relative (17 ± 9 percent) terms compared with that in normal subjects (p <0.02 and <0.005, respectively). The shortened rapid filling phase was accompanied by an absolute (9.2 ± 2.9 mm; p <0.05) and relative reduction (50.6 ± 11.8 percent; p <0.001) in left ventricular dimensional increase (Fig. 5). There was no difference among the three groups in duration of the slow filling period and dimensional change during this period (Fig. 6). During atrial contraction, left ventricular dimension in absolute (4.0 ± 1.5 mm; p <0.05) and in relative (23.1 ± 9.9 percent; p <0.05) terms was significantly greater than normal in chronic pressure overload. The duration of left ventricular filling due to atrial contraction was not different among the three groups (Fig. 6). A typical left ventricular echocardiogram and a dimension-time curve of the left ventricle with its normalized rate of change in a patient with chronic left ventricular pressure overload are illustrated in Figures 2 and 7.

Discussion

Left Ventricular Relaxation

Relaxation time index: In this study, as in previous studies by others[2,3,6–10] and by us,[11] the interval from minimal left ventricular dimension to the onset of mitral

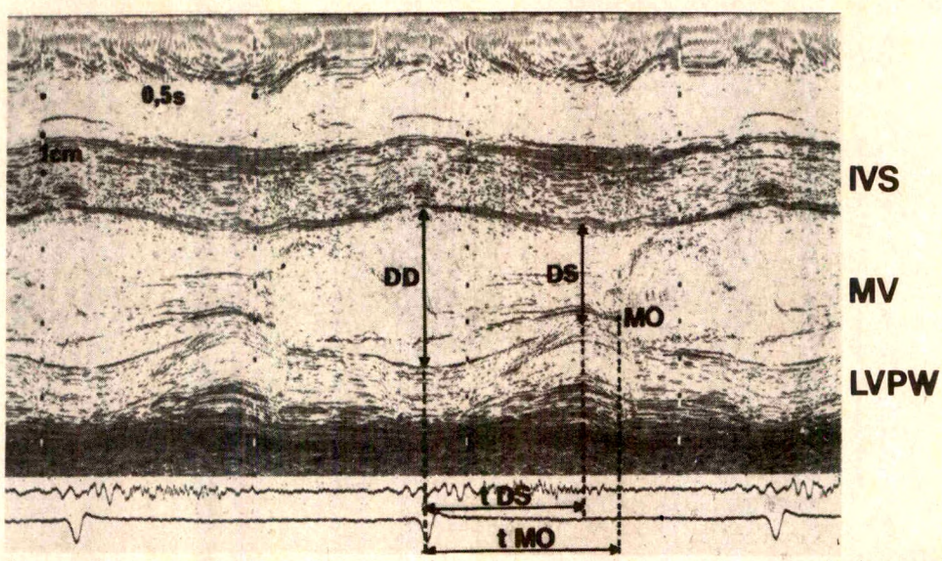

FIGURE 7. Echocardiogram of a patient with left ventricular hypertrophy due to aortic valve stenosis showing the interventricular septum (IVS), left ventricular posterior wall (LVPW) and mitral valve leaflets (MV). Mitral valve opening (MO) with regard to minimal left ventricular dimension (DS) is delayed. Unidentified abbreviations as in Figures 1 and 3.

valve leaflet separation was considered an index of the isovolumic relaxation period. This interval underestimates the true isovolumic relaxation period because closure of the aortic valve usually precedes minimal left ventricular dimension. In the presence of a true isovolumic relaxation period, mitral valve opening may even start shortly before the minimal left ventricular dimension is reached, as has also been reported by others.[2,3,7] Although the relaxation time index is not identical with true isovolumic relaxation time, we found a significant correlation between the relaxation time index (Y) and the true isovolumic relaxation time (x), measured from A_2 to mitral valve opening ($Y = 1.10x - 22$; $r = 0.8$) and, therefore, we believe that the time interval between minimal left ventricular dimension and mitral valve opening may be considered an index of the duration of the left ventricular isovolumic relaxation. Particularly in patients with prolonged relaxation time we often found that the dicrotic notch of the aortic pressure curve coincided with minimal left ventricular dimension (Fig. 8 and 9). Simultaneous recordings of the left ventricular echocardiogram and left ventricular as well as aortic pressure revealed that patients with normal left ventricular function manifest only a slight change in dimension during isovolumic relaxation (Fig. 8).[12,13]

Normal subjects: The relaxation time index (minimal left ventricular dimension to mitral valve opening) was 13 ± 15 ms in normal subjects. This value was only slightly different from values obtained by others using a computerized technique to evaluate left ventricular echograms.[2,3,6,7,10] During this time interval, only a small increase in left ventricular dimension of 0.6 ± 0.5 mm was noted. For the whole of the isovolumic relaxation period, Gibson et al.[12] could not demonstrate any significant change in diameter in normal subjects using pressure-dimension loops. An example of such a loop with only a small change in left ventricular dimension during isovolumic relaxation in one of our normal subjects is shown in Figure 8.

Left ventricular hypertrophy: In contrast to the normal subjects, patients with hypertrophic obstructive cardiomyopathy as well as patients with chronic left ventricular pressure overload showed a significant prolongation of the relaxation time index. This has been previously shown in patients with hypertrophic obstructive cardiomyopathy, but not in patients with chronic pressure overload.[2,3] The average value in hypertrophic obstructive cardiomyopathy was 93 ± 37 ms, which is slightly greater than that found by Sanderson et al.[2] (76 ms) and Sutton et al.[3] (71 ± 31 ms), who used a similar technique for the analysis of the echocardiogram.

Left ventricular diameter change: A further abnormality of left ventricular relaxation in patients with different forms of left ventricular hypertrophy concerns left ventricular diameter change during the period defined by the relaxation time index. This change, in di-

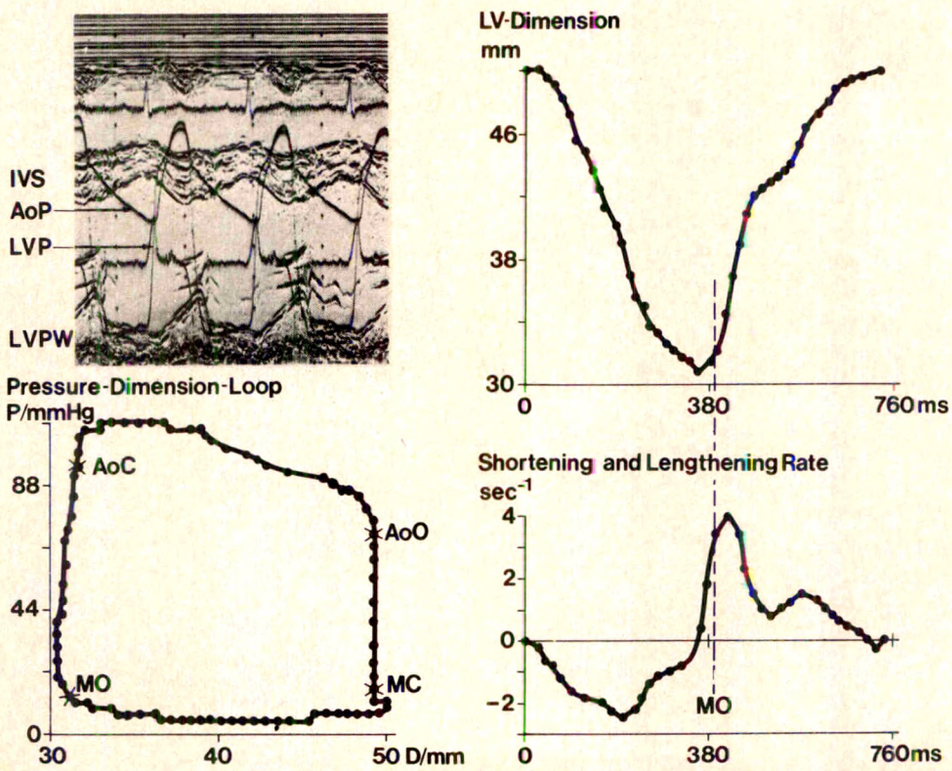

FIGURE 8. Left ventricular echocardiogram and simultaneous recording of the left ventricular (LVP) and aortic pressure (AoP) in a normal subject. Mitral valve opening (MO) coincides with the closure of the aortic valve (AoC). During isovolumic relaxation no significant dimensional change occurs, as can be easily recognized from the pressure-dimension loop and the left ventricular dimension-time curve. AoO = aortic valve opening; D = dimension; IVS = interventricular septum; LVPW = left ventricular posterior wall; MC = mitral valve closure; P = pressure.

ameter averaged 0.6 ± 0.5 mm in normal subjects, 4.0 ± 2.2 mm in patients with hypertrophic obstructive cardiomyopathy and 3.0 ± 1.8 mm in patients with chronic pressure overload. Because the mitral valve is still closed during this period and no aortic regurgitation was present, this increase in dimension by an average of 21 and 14 percent, respectively, with respect to the total diastolic dimensional change must be caused by a change in shape of the left ventricular cavity during the isovolumic relaxation phase. This finding was recently reported by Sanderson et al.[1] using frame by frame angiographic analysis in patients with hypertrophic obstructive cardiomyopathy.

Mechanism of changes in left ventricular hypertrophy: The underlying mechanism of the prolonged relaxation time and the associated change in shape is unknown. It has been suggested that the specific architecture of the myocardial fibers in hypertrophic obstructive cardiomyopathy might be responsible.[1] From our data, however, this seems unlikely because we could demonstrate that the same relaxation abnormality was also present to a somewhat lesser degree in patients with chronic left ventricular pressure overload, a condition in which no such disarrangement of myocardial fibers can be found.[14] It might be speculated that a significant increase in muscle mass, which is known to be associated with diffuse or subendocardial fibrosis, may cause abnormal left ventricular relaxation in both conditions.[14,15] Subendocardial ischemia, often present in severe left ventricular hypertrophy, may be an additional factor in the impairment in left ventricular relaxation. In animal experiments and under clinical conditions it has been shown that ischemia may delay left ventricular relaxation.[17,18,19]

Left Ventricular Filling

Normal subjects versus those with left ventricular hypertrophy: In our normal group, the percent diameter increase during the three phases of diastolic filling was in the same range as that previously reported by Decoodt et al.,[5] (62 ± 10 percent during the rapid filling phase, 22 ± 9 percent during the slow filling phase and 16 ± 10 percent due to atrial contraction. In hypertrophic obstructive cardiomyopathy and chronic pressure overload, we found the percent diameter change during the rapid filling phase equally reduced (to 54 ± 15 and 51 ± 12 percent, respectively). In accordance with the finding of Sanderson et al.,[2] the duration of the rapid filling phase was significantly shortened by about 30 percent in hypertrophic cardiomyopathy and by 23 percent in chronic pressure overload.

Hypertrophic cardiomyopathy versus left ventricular pressure load: In contrast to these data, Sutton et al.[3] found a prolongation of the rapid filling phase in the majority of patients with hypertrophic obstructive cardiomyopathy. In our opinion, this discrepancy may be partly due to the inclusion by these

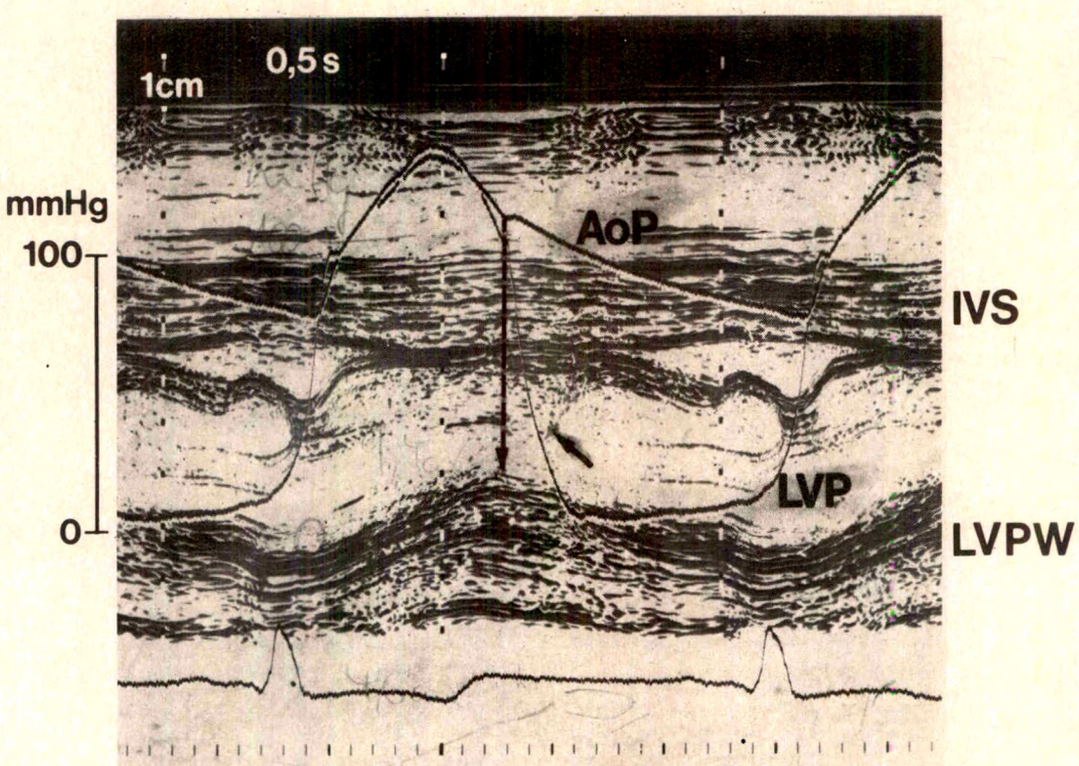

FIGURE 9. Left ventricular echocardiogram and simultaneous recording of left ventricular (LVP) and aortic (AoP) pressure in a patient with hypertrophic cardiomyopathy with no pressure gradient at rest. Mitral valve opening (**short oblique arrow**) is markedly delayed with regard to minimal left ventricular dimension (**long vertical arrow**), which in this case coincides with aortic valve closure. IVS = interventricular septum; LVPW = left ventricular posterior wall.

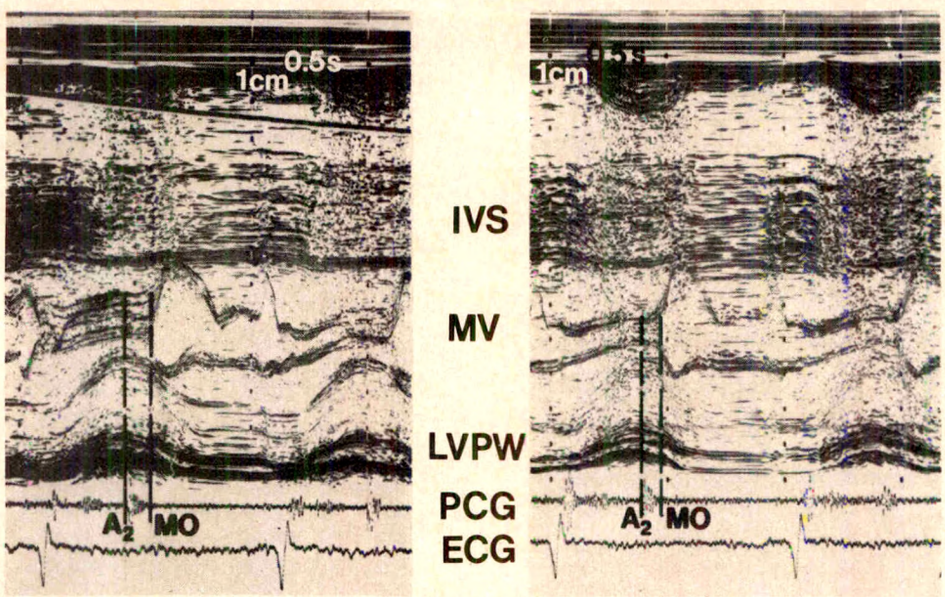

FIGURE 10. Left ventricular echocardiogram of a patient with hypertrophic cardiomyopathy and no left ventricular pressure gradient at rest before (**left**) and 5 minutes after an intravenous bolus injection of 10 mg verapamil (**right**). The initially prolonged isovolumic relaxation phase (from the aortic component of the second heart sound [A_2] to mitral valve opening [MO]) shortens markedly. Systolic blood pressure did not change. ECG = electrocardiogram; IVS = interventricular septum; LVPW = left ventricular posterior wall; MV = mitral valve; PCG = phonocardiogram.

authors of the time interval from minimal left ventricular dimension to mitral valve opening in their measurement of the rapid filling phase. In the absence of any significant difference among the three groups regarding the slow filling phase, the reduced dimensional increase during the rapid filling phase was compensated by a more vigorous atrial "kick" (23 ± 9.9 percent) in patients with chronic left ventricular pressure overload, resulting in a normal end-diastolic left ventricular dimension. In hypertrophic obstructive cardiomyopathy, however, the end-diastolic dimension remained below "normal," which suggests that the compensatory mechanism during the slow filling phase and during atrial contraction could not fully make up for the lack in early diastolic increase in dimension. This might be due to the absence of thinning of the intraventricular septum during atrial contraction that is frequently observed in patients with hypertrophic obstructive cardiomyopathy.

Clinical Implications

In patients with hypertrophic obstructive cardiomyopathy and chronic left ventricular pressure overload, the relaxation period is abnormally prolonged. This prolongation is often associated with a reduced increase in diameter during a shortened rapid filling phase in both conditions. Nonetheless, in chronic pressure overload the end-diastolic dimensions were normal, because atrial contraction compensates for the reduction in early diastolic filling. However, in hypertrophic obstructive cardiomyopathy, the compensatory mechanism fails to achieve a normal left ventricular end-diastolic dimension.

Calcium flux antagonists: Some investigators suggest that prolonged relaxation caused by ischemia is responsible for a diminished early diastolic filling of the left ventricle.[19–22] If we accept this hypothesis, therapeutic considerations should be directed toward an improvement of left ventricular relaxation. Recent experimental work[23] on the effects of calcium flux antagonists as modifiers of ischemia induced prolongation of myocardial relaxation rate encouraged us to study the acute effect of intravenous (0.15 mg/kg) verapamil (Knoll A. G., Lüdwigshafen, West Germany) on left ventricular relaxation time. Preliminary results in 10 patients with hypertrophic cardiomyopathy revealed a 28 percent decrease in left ventricular isovolumic relaxation time from 94 ± 10 to 68 ± 15 ms ($p < 0.001$) in the absence of any significant difference in heart rate, blood pressure, end-systolic left ventricular dimension or the time interval beginning from the R wave peak to aortic valve closure. An individual example of improved left ventricular relaxation time is shown in Figure 10. However, further studies are needed to evaluate the clinical significance of this new therapeutic approach in patients with hypertrophic cardiomyopathy.

The Heterogeneity of Hypertrophic Cardiomyopathy: An Autopsy and One Dimensional Echocardiographic Study

JEANNE Y. WEI, MD, PhD
JAMES L. WEISS, MD, FACC
BERNADINE H. BULKLEY, MD, FACC

Baltimore, Maryland

Although echocardiography is sensitive in detecting genetically determined idiopathic hypertrophic subaortic stenosis with the two major criteria of systolic anterior motion of the mitral valve and asymmetric septal hypertrophy, the predictive value of these findings in a nonselected population remains uncertain. A study was made of nine consecutive patients with an echocardiographic diagnosis of idiopathic hypertrophic subaortic stenosis who underwent autopsy between 1975 and 1979. The patients ranged in age from 1 month to 74 years (average 53), and six were women. Seven had systolic anterior motion of the mitral valve, and one pseudo systolic anterior motion, eight had asymmetric septal hypertrophy, and three had mid systolic aortic valve closure. All nine had a systolic murmur at the cardiac apex and an abnormal electrocardiogram. At autopsy only two patients had asymmetric septal hypertrophy and myocardial fiber disarray; the other seven had no evidence of hypertrophic cardiomyopathy on gross examination or light microscopy. Of these seven, two had concentric left ventricular hypertrophy, one coronary atherosclerosis, one cardiac amyloidosis, and three no cardiac disease. These data suggest that systolic anterior motion of the mitral valve and asymmetric septal hypertrophy may be sensitive but are poorly predictive of idiopathic hypertrophic subaortic stenosis in the general hospital population. Because these two findings may be observed even in patients with a normal heart, an echocardiographic diagnosis of idiopathic hypertrophic subaortic stenosis based on these criteria should be made with caution.

With the widespread recognition of idiopathic hypertrophic subaortic stenosis as a disease entity, one dimensional echocardiography has played a key role in its diagnosis and in evaluation of therapy.[1–4] The two major echocardiographic features in this syndrome are systolic anterior motion of the anterior mitral leaflet and asymmetric septal hypertrophy.[2–7] Other characteristic findings include septal hypokinesia,[8] anterior displacement of the mitral valve apparatus[9] and mid systolic closure of the aortic valve.[10] Although it has been thought that this noninvasive method is sensitive and specific for the detection and therapeutic assessment of hypertrophic cardiomyopathy,[2–4,11–14] the predictive value of these echocardiographic features in a population not selected for hypertrophic disease has not been determined. To assess the predictive value of these findings, we studied the nine consecutive patients with an echocardiographic diagnosis of hypertrophic cardiomyopathy who came to autopsy at this institution between 1975 and 1979.

Methods

Patients: All patients with an echocardiographic diagnosis of idiopathic hypertrophic subaortic stenosis who were listed in the autopsy files of The Johns

Hopkins Hospital and had undergone pathologic study between 1975 and 1979 were included in this study. The clinical, echocardiographic and morphologic data in these nine patients were analyzed. Clinical features including symptoms, pertinent physical findings and electrocardiographic changes were reviewed. Echocardiographic studies had been obtained 1 day to 18 months (median 14 days) before the patient's death.

Echocardiography: The echocardiographic examination was performed with the patient in a supine or left semilateral position, using a Smith-Kline Ekoline 20 A ultrasonoscope with a diameter of 1.25 cm and a 2.25 megahertz Aerotech transducer. The echocardiograms were recorded on a Cambridge strip chart recorder or Honeywell direct writing recorder. The thickness of the interventricular septum was measured in diastole using the leading edge method for thickness (at the first deflection of the QRS complex) and in systole (minimal left ventricular diameter), below the tips of the mitral valve leaflets; left ventricular posterior wall thickness was measured at the level of the chordae tendineae.[13] End-diastolic (at the peak of onset of the R wave in the QRS complex) and end-systolic (at the smallest septal-posterior wall distance) left ventricular internal dimensions were measured below the tips of the mitral valve leaflets. Systolic

Clinical Information in Nine Patients With Echocardiographic Features of Idiopathic Hypertrophic Subaortic Stenosis*

Case no.	Age (yr) & Sex	Past History	Family History of Heart Disease	Presenting Complaint	Physical Findings	ECG Changes	Chest Radiograph	Course
1	74F	Recurrent GI bleeding, anemia, thrombocytopenia, dysphagia	Negative	Weight loss, fever, night sweats, dysphagia	Fever, tachypnea, edema, SM at LLSB and apex	S-T and T wave changes	Focal fibrosis	Intraabdominal hemorrhage, sepsis, respiratory failure, GI bleeding
2	50F	Hypertension, chest pain, prior MI, palpitations	Negative	None	SM at LLSB and apex, S_4	Transient Q in V_1-V_3, poor R wave progression	WNL	Sudden death at home
3	70M	COPD, MI, hypertension, chest pain	Coronary artery disease	Nausea, vomiting, weight loss, dehydration	Tachycardia, rales, edema, SM at LLSB and apex, rapid rising carotids	LVH, S-T and T wave changes	WNL	Pulmonary emboli
4	66F	Hypertension, obesity, unstable angina	Negative	New murmur	Tachycardia, SM at LLSB and apex	Q in II, III, aVF	WNL	Post coronary surgery, hypotension, cardiac arrest
5	71F	Thyroidectomy	Negative	Loss of vision, altered mental status, syncope, fever	Fever, tachycardia, disoriented, SM at LLSB and apex, S_4	Q in V_1-V_3	WNL	Fever, deteriorating mental status, hypotension, cardiac arrest
6	74F	Good health	Negative	Dyspnea, dysphagia, altered mental status, dehydration, chest pain	Fever, tachycardia, tachypnea, disoriented, SM at LLSB and apex, rapid rising carotids	LAD, poor R wave progression	Diffuse infiltrate	Sepsis, hypotension, respiratory arrest
7	0.1M	Congestive heart failure	Multiple intrauterine deaths	Failure to thrive	SM at LLSB and apex, S_3	Poor R wave progression	Pulmonary congestion, cardiomegaly	Intraoperative death
8	53F	GI bleeding, congestive heart failure	Coronary artery disease	Dyspnea, edema	Tachycardia, tachypnea, SM at LLSB and apex, S_4, rales, edema	1° HB, poor R wave progression, S-T and T wave changes	Pulmonary congestion, cardiomegaly	GI operation, congestive heart failure, cardiac arrest
9	15F	Good health	IHSS, sudden death	None	SM at LLSB and apex	1°HB, Q in II, III, aVF, V_5, V_6, S-T and T wave changes	Cardiomegaly	Sudden death at home

* The physical findings, electrocardiographic and chest X-ray changes are from the most recent hospital visit before death, 2 weeks and 6 months for Patients 2 and 9, respectively.

COPD = chronic obstructive pulmonary disease; 1° HB = first degree heart block; GI = gastrointestinal; IHSS = idiopathic subaortic hypertrophic stenosis; LAD = left axis deviation; LLSB = left lower sternal border; LVH = left ventricular hypertrophy; MI = myocardial infarction; SM = systolic murmur; WNL = within normal limits.

septal excursion was measured as the distance of posterior movement of the left septal echo in systole. Ejection fraction was calculated using the left ventricular end-diastolic and end-systolic dimensions.[15]

Echocardiographic criteria for diagnosis of idiopathic hypertrophic subaortic stenosis included (1) systolic anterior motion of the anterior mitral leaflet, (2) asymmetric septal thickness with a septal to posterior wall thickness ratio greater than 1.3,(3) decreased systolic septal thickening (less than 30 percent), (4) decreased systolic septal excursion (less than 6 mm), and (5) mid systolic aortic valve closure. Other echocardiographic features were a small left ventricular cavity and left atrial enlargement.

Pathology: In eight patients, the heart, gross photographs, and at least five histologic sections of myocardium stained with hematoxylin-eosin, were examined. The interventricular septal thickness at one-third the distance between the aortic valve and left ventricular apex, the left ventricular posterior wall thickness directly behind the posterior mitral valve leaflet, and right ventricular maximal wall thickness were measured.[16] Blocks of myocardium were taken from the sites of measurement of the free wall and septal thickness as well as from the anterior and posterior left ventricular free walls and the septum in the left ventricular outflow tract. The histologic sections were graded with respect to extent of muscle fiber disarray. Stereoscopic radiographs of postmortem coronary arteriography were also reviewed. In one patient the autopsy examination was limited to needle biopsy specimens that provided the unsuspected diagnosis of cardiac amyloid and systemic amyloidosis.

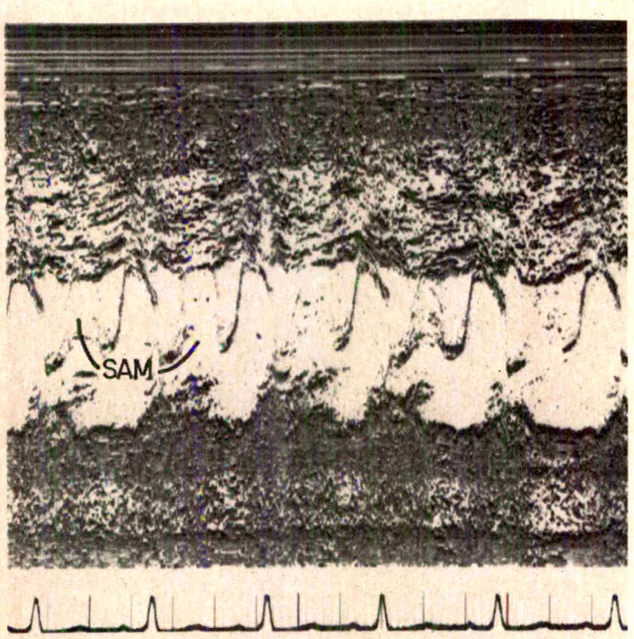

FIGURE 1. Case 2. Echocardiogram of a 50 year old woman who had a clinical diagnosis of hypertrophic cardiomyopathy. She had dyspnea, chest pain and, on examination, a grade 3/6 systolic murmur along the left lower sternal border that increased dramatically in intensity with the Valsalva maneuver. She had an active precordium and full early rapidly rising and falling carotid pulses. The echocardiogram shows a small left ventricular cavity and prominant systolic anterior motion of the mitral leaflet (SAM) which makes contact with the septum in systole. Although there is the suggestion of a thickened septum, an echocardiogram of adequate technical quality to measure accurately interventricular septal thickness could never be obtained. She had symptomatic improvement with propranolol therapy but died suddenly several months later. Findings in her heart at autopsy are shown in Figure 2.

Results

Clinical features (Table I): The patients ranged in age from 1 month to 74 years (average 53 years); seven were female, and two were male (one a male infant). Two patients had enjoyed good health previously. Four had had long-standing hypertension, three were diagnosed to have had one or more myocardial infarctions and three had experienced episodic chest pain. Nausea had been present in three, and recurrent upper gastrointestinal bleeding of unknown origin in two. One patient (Case 9) had a family history of hypertrophic cardiomyopathy and sudden death, and another (Case 7) had a maternal history of multiple intrauterine deaths. Three patients had presented with hallucinations, altered mental status and dehydration, two with increasing congestive heart failure, one with weight loss, fever, night sweats and dysphagia, two with sudden unresponsiveness at home and one with hypotension after coronary arterial bypass surgery.

On physical examination, abnormal vital signs included fever (three patients), tachycardia (five patients) and tachypnea (three patients). Basilar rates were noted in two patients, and three had peripheral edema. All nine patients had a loud systolic murmur at the left lower sternal border and apex that radiated widely to the carotid arteries and axilla in two. In at least five patients the murmur was holosystolic and increased with the Valsalva maneuver. The electrocardiogram was abnormal in all nine, with changes suggestive of anterior wall disease or old anterior infarction in six, and nonspecific diffuse changes in three. The chest radiograph was normal in four, showed cardiomegaly in three and focal and diffuse interstitial infiltrates in one. Leukocytosis and sepsis were present in two, recurrent gastrointestinal hemorrhage in two and episodes of hypotension in four. Three patients had a hematocrit of less than 35.

Echocardiograms (Table II): These demonstrated systolic anterior motion of the anterior mitral valve leaflet in seven (Fig. 1 and 2) and pseudo systolic anterior motion (anterior motion of the mitral anulus) in one. Eight patients had an asymmetrically thickened septum, with a ratio of septal to posterior wall thickness of 1.3 or more (Fig. 3 and 4). In one of these eight, an infant, the measurement was less clear but asymmetric septal hypertrophy was nevertheless diagnosed (Fig. 5). Decreased septal thickening (less than 30 percent) was present in six, and decreased systolic septal excursion occurred in five. Mid systolic aortic valve closure was noted in three patients (Fig. 3). Seven had a small hypercontractile left ventricle and three had an enlarged left atrium.

Morphologic findings (Table III): Left ventricular posterior free wall thickness measurements ranged between 0.6 and 1.8 cm and revealed considerably greater thickness than the measurement obtained with echocardiography. Ventricular septal thickness (1.0 to

* Septal thickness could not be precisely measured.
† Serial echocardiographic studies are in chronologic order, with the most recent study last.
AV = aortic valve, EDD = end-diastolic dimension; ESD = end-systolic dimension; IVS = interventricular septum; PW = left ventricular posterior wall; SAM = systolic anterior motion of anterior mitral leaflet; VS = interventricular septum; − = absent; + = present.

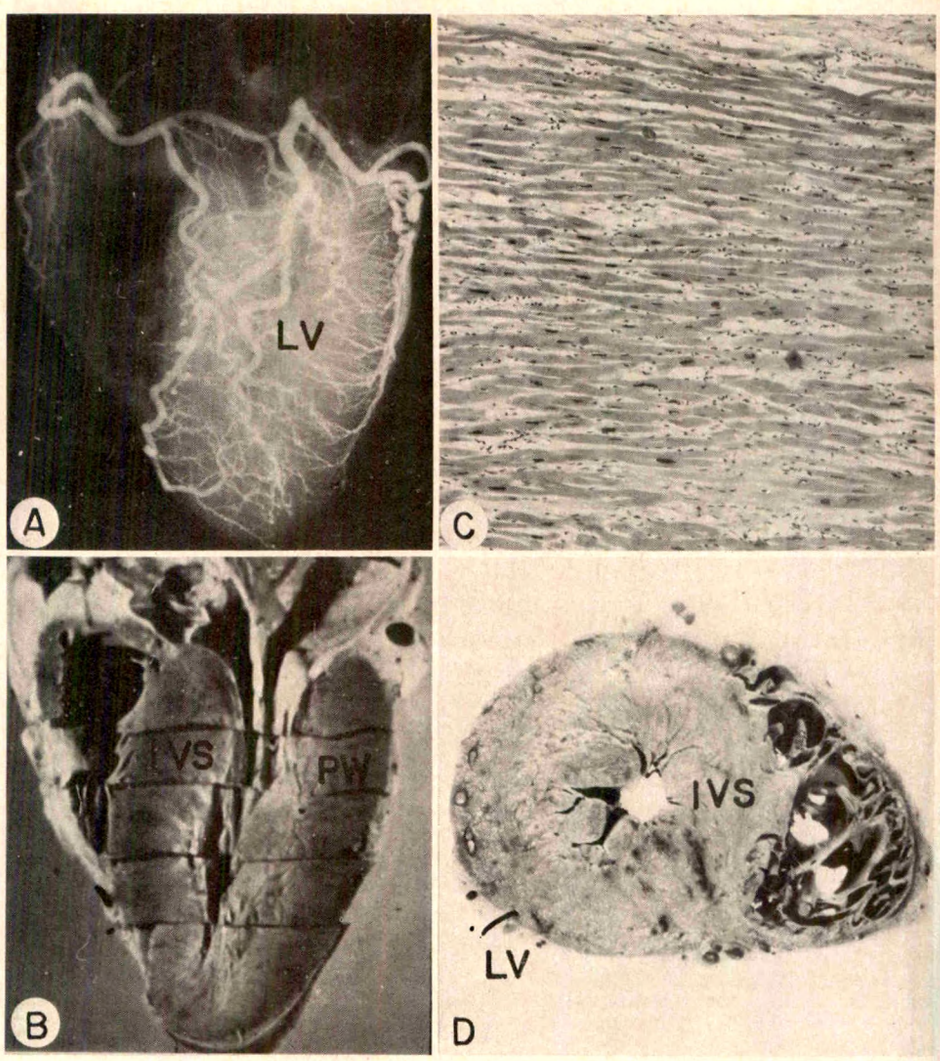

FIGURE 2. Case 2. Same patient as in Figure 1. **A**, postmortem angiogram showing normal coronary arteries, a small left ventricular (LV) cavity and a symmetric mildly hypertrophied left ventricular wall. The thickness of the interventricular septum (IVS) is equal to that of the posterior wall (PW) (**B** and **D**). Histologic examination of the myocardium (**C**) of both the septum and left ventricular free wall revealed normal findings. RV = right ventricle. (Hematoxylin-eosin ×65, reduced by 17 percent [**C**].)

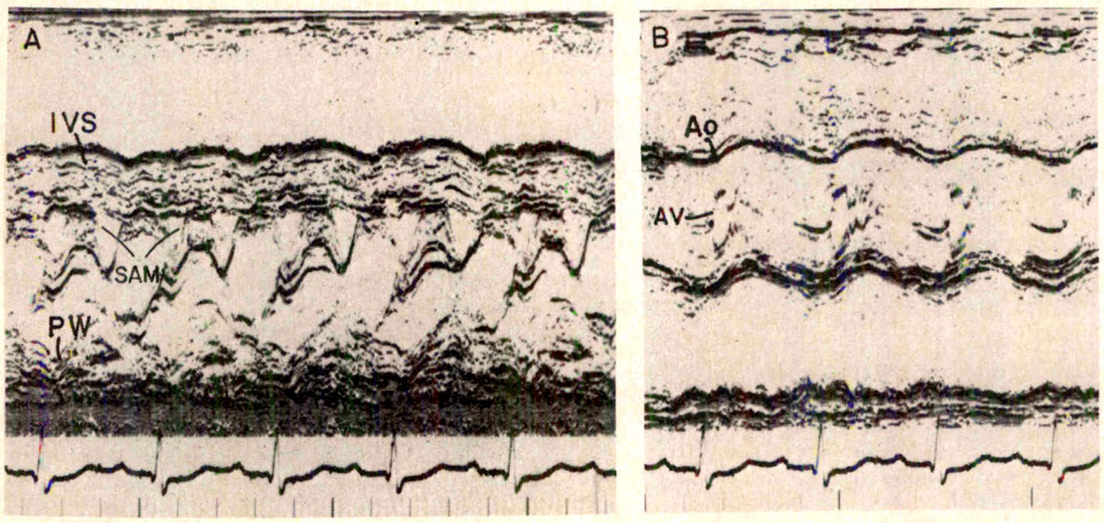

FIGURE 3. Case 3. Echocardiogram of a 70 year old man who had a history of systemic hypertension, chest pain, dyspnea, dizziness and syncope, and possible myocardial infarction. He also had long-standing chronic obstructive pulmonary disease, bibasilar rales and a grade 4/6 holosystolic murmur in the echocardiogram. **A**, the left ventricular cavity is small, the interventricular septum (IVS) measures 1.8 cm and the posterior wall (PW) 0.8 cm, and the former shows decreased systolic thickening. Systolic anterior motion of the mitral valves (SAM) is present. **B**, early aortic valve (AV) closure is present. It was concluded that his symptoms of dyspnea, chest pain, and syncope were caused by idiopathic hypertrophic subaortic stenosis, manifesting itself for the first time in old age. He died suddenly of what at autopsy proved to be pulmonary thromboembolism. Ao = aorta.

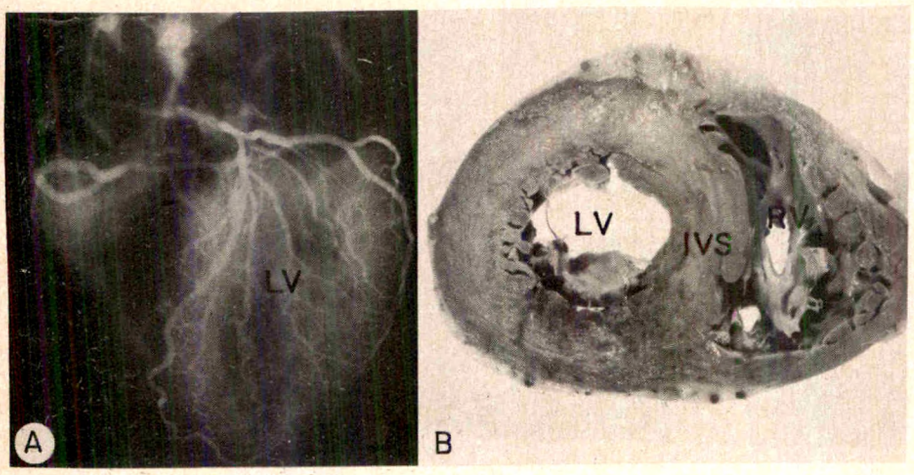

FIGURE 4. Case 3. Same patient as in Figure 3. **A**, postmortem cardiac angiogram and in **B**, a transverse slice of heart through the left (LV) and right (RV) ventricle. This heart is symmetrically hypertrophied, weighing 560 g with a wall thickness of 1.8 to 1.9 cm. The myocardial histologic features were normal. No critical narrowings are present in the coronary arterial tree. IVS = interventricular septum.

3.5 cm) appeared to correlate more closely with the respective echocardiographic measurements. Heart weight, available in seven cases, ranged from 310 to 560 g (mean 413). A septal endocardial plaque in the left ventricular outflow tract was present in three patients. The configuration of the ventricular septum, as determined from the radiographs and heart specimens, was normal (concave toward the left ventricle) in the transverse plane in eight patients. But in seven patients, the curvature was convex to the left ventricle in the apex to base plane.

The ratio of ventricular septal to posterior wall thickness was greater than 1.3 (1.6 and 1.9, respectively) in two patients, and in both multiple foci of markedly disordered and hypertrophied myocardial cells were noted (Fig. 5). One of these two patients (Case 9) had a positive family history of hypertrophic obstructive cardiomyopathy and sudden death and the other (Case 7) a maternal history of multiple intrauterine deaths. An area of marked myocardial thinning was noted at the cardiac apex in one patient (Case 9), and histologic study of this area demonstrated extensive fibrosis of the myocardium and a prominent overlying endocardial fibroelastosis. In both patients histologic examination of the interventricular septum revealed areas of marked fiber disarray including a whirling or circular arrangement of the hypertrophied fibers and focally enlarged and thickened intramural coronary arteries. These two patients with anatomic evidence of familial idiopathic hypertrophic subaortic stenosis were the only two to have come to autopsy at this institution with antemortem echocardiographic findings consistent with that diagnosis.

In contrast, the other seven patients who did not have asymmetric septal hypertrophy manifested only a minimal degree of muscle fiber disarray characteristic of normal hearts and had normal intramural coronary arteries. Of these seven patients without asymmetric septal hypertrophy or myocardial fiber disarray, two had concentric left ventricular hypertrophy only (Fig. 2), one had severe coronary atherosclerosis with cardiac hypertrophy and one had cardiac amyloidosis. In this latter patient in whom only biopsy needle tissue samples were authorized, there was hypertrophy of myocardial fibers with large amounts of interstitial and vessel wall amyloid. The other three patients had no evidence of cardiac disease. Two of these three patients had myeloproliferative disorders, myelofibrosis with myeloid metaplasia in one and an unusual intravascular hematologic malignancy of myeloid origin in the other. The third patient had widely metastatic carcinoma with pneumoperitoneum and dead bowel. Sepsis was present in two and pneumonia with adrenal insufficiency due to intraadrenal hemorrhage in one.

Discussion

The form of hypertrophic cardiomyopathy also known as asymmetric septal hypertrophy (ASH) or idiopathic hypertrophic subaortic stenosis (IHSS) has characteristic morphologic features first described by Teare,[17] in which the septum is asymmetrically hypertrophied and the myocardium, especially of the septum,

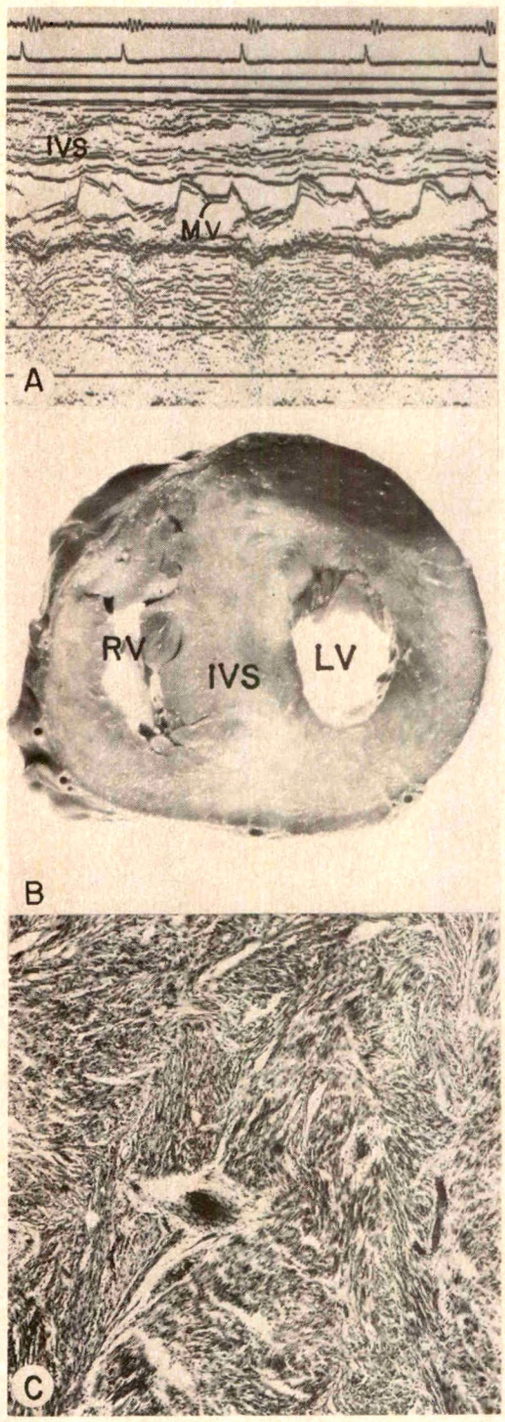

FIGURE 5. Case 7. **A**, an echocardiogram from a newborn infant who presented with congestive heart failure and a murmur suggesting mitral insufficiency. The left ventricular cavity is small and the interventricular septum (IVS) measures twice the thickness of the free wall. Systolic anterior motion of the mitral valve (MV) is not present. Because normal infants may have asymmetric septal hypertrophy, the diagnosis of idiopathic hypertrophic subaortic stenosis was not made until autopsy. At autopsy, marked asymmetric septal hypertrophy (**B**) and myocardial fiber disarray (**C**), most prominent in the septum, are observed; there were no other cardiac malformations or abnormalities. This was the only case in the study in which the clinical and echocardiographic diagnosis of idiopathic hypertrophic subaortic stenosis was not seriously suspected during life, and the one in which the echocardiographic finding during life and in retrospect were the most uncertain. (Hematoxylin-eosin ×65, [**C**], reduced by 28 percent.)

has marked fiber disarray. This form of hypertrophic cardiomyopathy, characterized and identified echocardiographically by its striking asymmetric hypertrophy, appears to be almost always genetic according to family studies performed using asymmetric septal hypertrophy as the criteria.[18] Another common echocardiographic feature of genetic hypertrophic cardiomyopathy is systolic anterior motion of the mitral valve.[2–5,9–11,18] In recent years several investigators[6,16] have suggested that an echocardiogram showing asymmetric septal hypertrophy and systolic anterior motion of the mitral valve virtually always means genetic asymmetric cardiac hypertrophy with anatomic asymmetric septal thickening and myocardial fiber disarray. After their observations were made, hypertrophic cardiomyopathy became a considerably more common clinical diagnosis. Largely on the basis of echocardiographic findings, this disease is being described in a host of asymptomatic patients with murmurs, as well as those with other cardiac disease such as aortic valve stenosis, acromegaly and systemic hypertension.[19]

Despite widespread reliance on echocardiography for the diagnosis of hypertrophic cardiomyopathy, morphologic validation of these echocardiographic findings is scarce. In this study, we examined at autopsy the hearts of nine patients who had the echocardiographic diagnosis of hypertrophic cardiomyopathy. Our findings indicate that the echocardiographic features of systolic anterior motion of mitral valve and asymmetric septal hypertrophy as well as mid systolic aortic valve closure and septal hypokinesia may occur in patients without familial hypertrophic cardiomyopathy or left ventricular hypertrophy and may even occur in patients with a normal heart. These findings require a reexamination of the meaning of the echocardiographic and morphologic markers thought to be highly specific if not pathognomonic for this heritable disorder of the heart.

Systolic anterior motion of the mitral valve: It has been thought that the echocardiographic finding of systolic anterior motion of the mitral valve reflects left ventricular outflow obstruction due to contact of the anterior mitral leaflet with an asymmetrically hypertrophied septum in a narrowed outflow tract. But this echocardiographic finding may occur in the absence of asymmetric septal hypertrophy[8,20,21] and without an outflow tract gradient.[8] Alternatively, it may reflect either systolic contact of the anterior mitral leaflet with the posterior papillary muscle that has been displaced above and in front of the mitral leaflets,[9,22] or contact of the anterior leaflet with the septum as a result of a cavity obliteration. Thus, it is possible that anterior motion of the mitral valve in systole at times may be due to hemodynamic forces generated in the left ventricle and on other occasions may indicate altered left ventricular geometry caused by an unusually small left ventricular cavity that may be either a functional or a fixed structural phenomenon. Therefore, in the setting of good ventricular function and a decreased left ventricular transverse dimension, whether due to asymmetric or concentric hypertrophy, decreased left ventricular volume as a result of reduced venous return or alteration in ventricular shape caused by other factors, systolic anterior motion of the mitral valve, even with septal contact, may occur with or without outflow obstruction.

Asymmetric septal hypertrophy: The echocardiographic finding of asymmetric septal thickening has also been noted in patients with congenital heart disease, ischemic heart disease, valvular heart disease and right ventricular hypertrophy, as well as in the normal human fetus, some newborns and normal weight lifters.[16,19,23–27] However, it appears that echocardiographic asymmetric septal thickening does not always reflect true anatomic asymmetry. It is not surprising that echocardiographic septal to free wall thickness ratios and actual measurements of the heart do not always coincide. The echocardiographic measurements are made in diastole whereas many hearts are fixed in systole. Because systolic posterior wall thickening may be much greater than systolic thickening, the echocardiographic diastolic thickness ratios would be expected to differ from systolic thickness ratios and, therefore, also from measurements in heart specimens that are fixed in systole.[28] Abnormalities of septal depolarization and contractility may also play a role. Furthermore, accuracy of echocardiographic measurements of septal thickness may be affected by multiple problems related to the cardiac anatomy and ultrasonic instrumentation.[29] An oblique projection of the transducer through the septum might create echocardiographic findings of asymmetry, and a small left ventricular cavity might make measurements difficult. Therefore, a discrepancy between the echocardiographic and morphologic septal measurements may be due to multiple factors.

Myocardial fiber disarray: The findings that increased myocardial fiber disarray was not present at autopsy in the interventricular septum in seven of nine patients is also evidence that these patients did not have genetic asymmetric hypertrophy of the heart. Although the finding of myocardial fiber disarray in the septum is also not a pathognomonic finding for genetic hypertrophic cardiomyopathy, extensive myocardial fiber disarray is found in only a few other disorders, including certain congenital abnormalities such as pulmonary and aortic atresia.[23,26] Since these congenital abnormalities can be readily excluded, the absence of myocardial fiber disarray of the septum in seven patients adds even further support to the spuriousness of the clinical diagnosis of genetic hypertrophic cardiomyopathy in the latter group.

Mid systolic aortic closure: This is another echocardiographic finding commonly associated with hypertrophic cardiomyopathy. Mid systolic aortic valve closure was observed in three patients in our study, two who had no evidence of genetic hypertrophic disease on gross examination or histologic study and one who had a normal heart morphologically. It has also been observed in patients with discrete subaortic stenosis.[30] Therefore, mid systolic closure of the aortic valve alone or in combination with systolic anterior mitral motion or asymmetric hypertrophy is also not specific for familial hypertrophic cardiomyopathy but likely reflects

TABLE IV

Categories of Hypertrophic Cardiomyopathy

Group	Type	Inherited	ASH	Concentric Hypertrophy	Marked Fiber Disarray	Secondary Hypertrophy	Hypercontractile State
I	Idiopathic—asymmetric	+	+	−	+	−	+
II	Idiopathic—symmetric	?	−	+	−	−	+
III	Secondary	−	−	+	−	+	+
IV	Physiologic	−	−	−	−	−	+

ASH = asymmetric septal hypertrophy.

any state in which almost all ejection of blood occurs early in systole. These observations do not negate the value of asymmetric septal hypertrophy and abnormal systolic anterior mitral movement and other commonly observed echocardiographic findings as useful clinical markers of hypertrophic disease. But, like most clinical tools, including the electrocardiogram or chest radiograph, the echocardiogram must be viewed in full clinical context, and a diagnosis of a cardiomyopathy and especially a genetic one should not be made on the basis of one laboratory test.

The spectrum of hypertrophic cardiomyopathy: Our data also suggest that the spectrum of hypertrophic cardiomyopathy may indeed be broader and more heterogeneous than suspected by some.[19] All patients with clinical findings of hypertrophic disease do not necessarily have an autosomal dominant disease and a heart with asymmetric hypertrophy or disorganized myocardial fibers. Our Patient 3 had a history, physical examination and echocardiographic findings suggestive of idiopathic hypertrophic subaortic stenosis and died suddenly from no other apparent cause. Although at autopsy her heart had features of hypertrophic disease, with a small left ventricular cavity, an outflow tract plaque and mild hypertrophy, she clearly did not have asymmetric septal hypertrophy or myocardial fiber disarray. Family members were not available for study, but her family history did not suggest cardiac disease. Thus, this case represents some form of hypertrophic disorder. Whether it was primary, secondary or familial is not clear, but it was surely not the same disease described by Teare. Further evidence for the heterogeneity of this disorder has recently appeared. HLA typing of patients with clinical hypertrophic cardiomyopathy[31] demonstrated that 60 percent were classified into one of two HLA groups (B5 or B12) and 50 percent of the first degree relatives of these patients had asymmetric septal hypertrophy. Patients without these HLA antigens had a small familial incidence of asymmetric septal hypertrophy and a striking incidence of systemic hypertension. Thus, these findings suggest the existence of at least two diseases within the disease category of hypertrophic cardiomyopathy: one associated with a specific HLA phenotype that is genetically transmitted, the other a sporadic nonheritable form that tends to be associated with systemic hypertension.

Our findings suggest that hypertrophic myocardial disease might well include four disease categories (Table IV). (1) The first is the commonly described Teare's disease, which appears to be inherited and might be referred to as idiopathic hypertrophic cardiomyopathy with asymmetric hypertrophy. Because asymmetry of the septum is a marker for this disease it is understandable that it has been possible to study it in depth even in mildly symptomatic or asymptomatic patients. (2) The second is idiopathic hypertrophic cardiomyopathy without asymmetric hypertrophy. This disease as yet does not have a good marker that would allow for noninvasive screening of large populations, although some patients with this disorder are probably being diagnosed as having familial hypertrophic disease with asymmetric hypertrophy. We have much to learn about this latter group. (3) A third category is secondary left ventricular hypertrophy in which a disease such as severe aortic stenosis or severe long-standing hypertension has led to a permanent restructuring of the heart and a functional state similar to hypertrophic cardiomyopathy that may persist despite relief of the underlying causative lesion. Lord Brock,[32] in his original report on hypertrophic disease, suggested that the disorder in many cases appeared to be secondary to either hypertension or aortic stenosis. The angiographic studies of Raizner et al.[33] showed that at least half of patients with the hemodynamic findings of hypertrophic disease have symmetric hypertrophy in the setting of systemic hypertension, suggesting an acquired hemodynamic derangement. (4) A fourth category of hypertrophic disease is the hypercontractile state in which hemodynamic features of hypertrophic cardiomyopathy may develop even in a normal heart under severe enough conditions of volume depletion or adrenergic stimulation.[20] Criley et al.[34] clearly demonstrated in their experimental animal work that intravenous isoproterenol could induce cavity obliteration and a subvalve outflow tract gradient in otherwise normal dog hearts. Others[35,36] have shown a similar phenomenon. Thus, it is with caution that one should make the diagnosis of a chronic cardiomyopathy based on clinical and even echocardiographic findings similar to those observed in genetic hypertrophic cardiomyopathy, especially in a patient in acute hemodynamic compromise due to sepsis, renal hemodialysis, volume depletion or intravenous pressor drug administration.

Implications: Echocardiographic asymmetric septal hypertrophy is poorly predictive for the form of hypertrophic cardiomyopathy initially described by Teare. Systolic anterior motion of the anterior mitral leaflet is not pathognomonic for this disorder, or even for a

cardiomyopathy, and may occur as a temporary state. Mid systolic aortic valve closure and decreased systolic septal thickening are also not specific for hypertrophic cardiomyopathy. Because all of these echocardiographic features, singly or in combination, may occur in patients with a normal heart, they may represent a physiologic response to certain hemodynamic or geometric alterations, or both, in some patients. They may also reflect a common intermediate state in the natural course of various diseases, such as amyloidosis or hypertension. Thus, a diagnosis of genetic hypertrophic cardiomyopathy or idiopathic hypertrophic subaortic stenosis of the morphologic type described by Teare[17] based on these echocardiographic features, even in the presence of a suggestive clinical presentation, should be made with caution in a general hospital population.

Hypertrophic Cardiomyopathy After Aortic Valve Replacement

Harefield, Middlesex, England

The association of hypertrophic cardiomyopathy and aortic valve disease is well documented. However, the new development of the syndrome late after valve replacement has not previously been described. We present six cases, all occurring in women aged 50 to 71 years who had evidence of hypertrophic cardiomyopathy 3 to 5 years after successful valve replacement. The preoperative hemodynamic lesion was aortic stenosis in four and aortic regurgitation in two. Before operation no patient showed evidence of hypertrophic cardiomyopathy as judged by the absence of (1) asymmetric septal hypertrophy (the septal/posterior wall ratio was less than 1.4:1.0 in each case); (2) systolic anterior mitral valve motion; (3) obliteration of the left ventricular cavity on angiography; and (4) an intraventricular pressure gradient. After valve replacement no patient had significant aortic regurgitation or was hypertensive. Four patients subsequently had recurrence of symptoms including dyspnea in four, angina in three and syncope in two. The electrocardiogram revealed reappearance of left ventricular hypertrophy in four patients and left bundle branch block in one. The echocardiogram disclosed asymmetric septal hypertrophy in six (septal/posterior wall ratio greater than 1.8:1.0), systolic anterior motion in three and evidence of inflow obstruction in three. At cardiac catheterization an intraventricular gradient of 36 to 60 mm Hg was demonstrated at rest in three patients, on provocation in one patient; two patients showed no gradient. Angiograms showed obliteration of the left ventricular cavity in all six patients (ejection fraction 0.84 to 0.93). Two patients had coronary artery disease. No patient had an aortic transvalve gradient at rest or with exercise.

The association between hypertrophic cardiomyopathy and aortic valve stenosis is well documented,[1–4] and some investigators have suggested that these two lesions may coexist in as many as 10 percent of patients with aortic stenosis.[5] However, there have been no previously reported cases of hypertrophic cardiomyopathy arising late after aortic valve replacement in patients who had no previous evidence of cardiomyopathy. In this study we describe six patients who first manifested hypertrophic cardiomyopathy 3 to 5 years after homograft replacement of the aortic valve.

Methods

Patients: Between September 1969 and May 1978, a total of 679 patients underwent homograft replacement of the aortic valve at Harefield Hospital. All patients were routinely followed up at this hospital at annual intervals with clinical, radiographic, electrocardiographic and echocardiographic examination except in 35 instances when follow-up information was obtained from the referring physician. During a follow-up period of 3 to 102 months (mean 47), six patients (0.9 percent) were found to have both echocardiographic and angiographic evidence suggesting hypertrophic cardiomyopathy. These six patients are the subject of this paper.

All six patients were women aged 50 to 71 years (mean 63) at the time of valve replacement. All were symptomatic and four of the six were in functional class III or IV of the New York Heart Association.[6] Presenting symptoms included angina and dyspnea in four patients, dyspnea alone in one patient and angina alone in one patient. In addition, one patient experienced recurrent attacks of effort syncope. The duration of symptoms ranged between 6 and 60 months (mean 23).

The electrocardiogram showed evidence of severe left ventricular hypertrophy in all patients, characterized by ST-T segment changes in the absence of digitalis together with an R wave voltage in the standard leads exceeding 20 mm or with the tallest R wave or the deepest S wave in the precordial leads exceeding 25 mm.

Preoperative cardiac catheterization procedures: Before operation all patients underwent right and left heart catheterization after overnight fasting and premedication with atropine, 0.01 mg/kg and diazepam, 0.15 mg/kg. After measurement of intracardiac pressures and, when appropriate, peak systolic aortic valve gradient, a single plane left ventricular cineangiogram was performed in the right anterior oblique projection; approximately 45 ml of 70 percent iothalamate sodium (Conray® 420) was injected at a flow rate of 15 ml, using a Contrac injector, and films were obtained at a rate of 50 frames/s using an Arriflex camera. Selective coronary angiography was performed using the Sones or Judkins technique. Cardiac output was determined with the direct Fick method, and body surface area to determine cardiac index was derived from nomograms. The aortic valve area was calculated from the formula of Gorlin and Gorlin.[7]

The dominant hemodynamic lesion was aortic stenosis in four patients and aortic regurgitation in two. The peak systolic aortic valve gradient in the four patients with aortic stenosis ranged between 70 and 130 mm Hg (mean 96), and all four had severe valve obstruction as judged by a calculated aortic valve area of less than 0.7 cm^2 (Table I). Aortic root angiography showed trivial aortic regurgitation in one of these patients. Left ventricular end-diastolic pressure was within the normal range in five patients and was marginally elevated in one. Ejection fraction ranged between 0.41 and 0.65 (mean 0.56).

Selective coronary angiography showed normal coronary arteries in five patients and 70 percent narrowing of luminal diameter of the proximal main circumflex artery in the sixth patient.

Echocardiography: M mode echocardiograms were performed preoperatively and then at annual intervals after valve replacement using a 2.25 megahertz focused transducer and a Smith Kline Echoline 20A in conjunction with a Cambridge multichannel recorder at a paper speed of 50 mm/s. *Left ventricular (LV) mass was calculated from the formula* LV mass = LV muscle volume × 1.05, where 1.05 = specific gravity of cardiac muscle and LV muscle volume = [(end-diastolic diameter) + (2 × diastolic wall thickness)]^3 − (end-diastolic diameter)^3.

Mitral diastolic closure rate was calculated as the EF slope of the mitral valve echogram. The maximal rate of left ventricular filling was calculated from the slope of left ventricular diameter against time. This measurement is derived using a pneumonic digitizer that is run along the left side of the interventricular septum of the M mode echo. As the pointer goes along the septum, the XY coordinates are recorded for each 0.5 mm along the X axis. These coordinates are stored in an Olivetti 652 programmable calculator and then the pointer is drawn carefully along the endocardial surface of the free ventricular wall. Again the XY coordinates are recorded in the calculator. The Y coordinates for each X value are subtracted from each other and the result gives a measure of the left ventricular diameter continuously throughout the cardiac cycle. This is then plotted out of an XY plotter and the maximal slope of left ventricular filling is then calculated.

The preoperative echocardiographic characteristics of the six patients are summarized in Table II. Left ventricular mass index was increased in all patients but the increase was somewhat smaller in those with aortic regurgitation. No patient had evidence of asymmetric septal hypertrophy as judged by a septal/posterior wall ratio of less than 1.4:1.0. As expected, maximal left ventricular filling rate was highest in the two patients with aortic regurgitation and was significantly higher than the normal range for this laboratory (130 ± 30 ml/s [mean ± standard error of the mean]). Maximal left ventricular filling rate was within the normal range in all four patients with aortic stenosis. Mitral diastolic closure rate was normal in all six patients and no patient showed evidence of systolic anterior motion of the mitral valve before operation.

Surgery: Homograft replacement of the aortic valve was performed in all patients using two suture lines with continuous coronary perfusion at 30° C.[8] One patient underwent combined aortic valve replacement and coronary arterial bypass grafting with a single graft to the diagonal branch of the left circumflex artery.

Postoperative cardiac catheterization procedures: Follow-up studies with right and left heart catherization, left ventricular cineangiography and coronary angiography were performed in all patients 2 to 6 years (mean 47 months) after valve replacement. Four patients were reinvestigated because of reappearance of symptoms. The remaining two patients, although free of symptoms, were reinvestigated as a result of the echocardiographic findings at routine follow-up coupled with the reappearance of electrocardiographic evidence of left ventricular hypertrophy in the electrocardiogram in the absence of valve dysfunction or hypertension.

Changes in left ventricular function were assessed by computerized radial analysis of segmental wall motion derived from the single plane angiogram.[9] The pre- and postoperative cineangiograms were projected on a Vanguard projector, and end-diastolic and end-systolic frames were digitized using an ultrasonic coordinate converter (Graf/Pen) on line with an HP2100A computer. Ejection fraction was determined using the single plane area-length method.[10] End-diastolic and end-systolic frames were then superimposed using the mid point of the aortic valve and the geometric center of gravity of the end-systolic frame as fixed reference points.[9] Radials were automatically plotted from the center of gravity to the ventricular perimeter at 4° increments in a clockwise direction

TABLE I

Preoperative Hemodynamic Characteristics of the Six Patients

Peak systolic aortic valve gradient (mm Hg)	70–130 (mean 96)
Aortic valve area (cm^2)	0.42–0.67 (mean 0.46)
Left ventricular end-diastolic pressure (mm Hg)	5.0–16.0 (mean 10.0)
Cardiac index (liters/min per m^2)	1.2–2.7 (mean 1.9)
Ejection fraction	0.41–0.65 (mean 0.56)
Coronary arteriography	Normal, 5 patients; single vessel disease, 1 patient

starting at the mid point of the aortic valve. Segmental wall motion was expressed as the percent change in length of such radials from end-diastole to end-systole and was plotted against the radial angle around the ventricular perimeter. An abnormality was defined as five consecutive radials (20° or 5 percent of the ventricular perimeter) greater than 2 standard deviations outside control values obtained in a group of normal angiograms (see Fig. 9).

Results

Symptoms: The six patients have now been followed-up for 48 to 72 months (mean 58 months) after valve replacement. Two years after valve replacement, all patients were entirely free of symptoms. However, at the time of latest follow-up, four patients had recurrent symptoms that included dyspnea in four, angina in three and multiple episodes of effort syncope in two patients. Repeated Holter tape electrocardiographic monitoring in these latter two patients failed to demonstrate a rhythmic change as a cause of the syncopal attacks. Standing and supine blood pressure was within the normal limits for age in all six patients.

Electrocardiography: Similarly, 2 years after valve replacement all patients manifested complete regression of the signs of left ventricular hypertrophy in the electrocardiogram, although two patients showed nonspecific T wave inversion in the anterolateral leads. However, at the time of latest follow-up the electrocardiogram disclosed reappearance of left ventricular hypertrophy in four patients; the condition was severe in two as judged from both voltage changes and reappearance of ST-T abnormalities that had previously returned to normal. Two patients had left ventricular hypertrophy as assessed from voltage criteria alone and one patient had left bundle branch block 3 years after valve replacement. The electrocardiogram continues to show normal findings in one patient.

Echocardiography: Serial changes in echocardiographically derived left ventricular mass are shown in Figure 1. The left ventricular mass index decreased in only one patient with aortic stenosis within the 1st year after valve replacement. In the remaining five patients there was no significant change in left ventricular mass. With the passage of time there was a steady increase in left ventricular mass in all patients although this was less marked in the two patients with aortic regurgitation. At the time of latest follow-up left ventricular mass ranged from 166 to 328 g/m^2 (mean 253); these values were significantly greater ($p < 0.001$) than preoperative values. The increase in left ventricular mass was particularly marked in two patients with aortic stenosis (Table II).

Serial changes in systolic septal/posterior wall thickness are shown in Figure 2. Before operation, no patient had a septal/posterior wall ratio of greater than 1.4:1.0, and values ranged from 1.1:1.0 and 1.4:1.0. Two years after valve replacement there was a significant increase in septal thickness, and septal/posterior wall ratio varied between 1.6:1.0 and 2.2:1.0. At the time of latest follow-up, no patient had a systolic septal/posterior wall ratio of less than 1.8:1.0. In each case the increase in septal to posterior wall ratio was due to increased septal thickening rather than to a decrease in posterior wall thickness.

Echocardiographically determined ejection fraction preoperatively ranged between 0.41 and 0.66 (mean 0.56). In the four patients with aortic stenosis, ejection fraction had increased significantly 2 years after valve replacement; values ranged from 0.70 to 0.78 (mean 0.75) ($p < 0.001$) (Fig. 3). At 4 years after operation there was a further significant increase in ejection fraction in this group ($p < 0.05$) with ejection fraction now ranging between 0.74 and 0.89 (mean 0.82). Changes in ejection fraction in the two patients with aortic regurgitation followed a rather different pattern. In one ejection fraction increased from 0.41 before operation to 0.87 1 year after operation. The ejection fraction in this patient continued to increase and at the time of latest follow-up (4 years after valve replacement), it is 0.97. The second

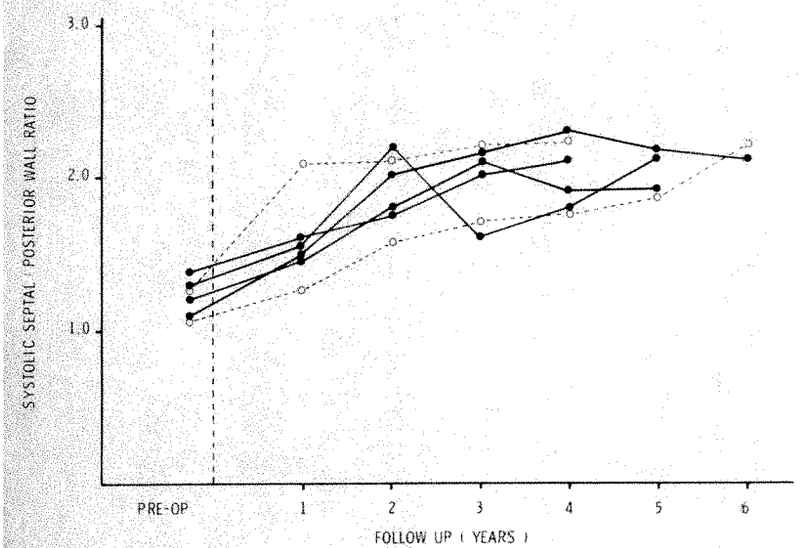

FIGURE 2. Serial changes in left ventricular septal/posterior wall thickness ratio in six patients after aortic valve replacement. **Closed circles** = aortic stenosis; **open circles** = aortic regurgitation.

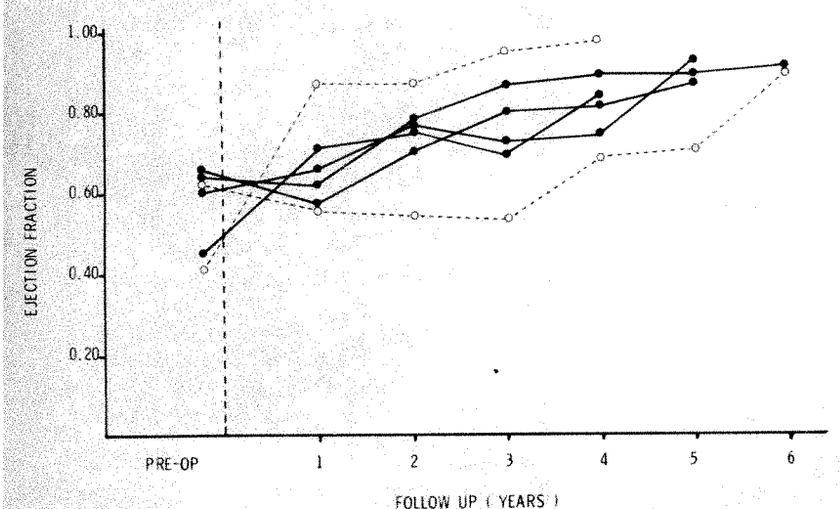

FIGURE 3. Serial changes in echocardiography derived ejection fraction in six patients after aortic valve replacement. **Closed circles** = aortic stenosis; **open circles** = aortic regurgitation.

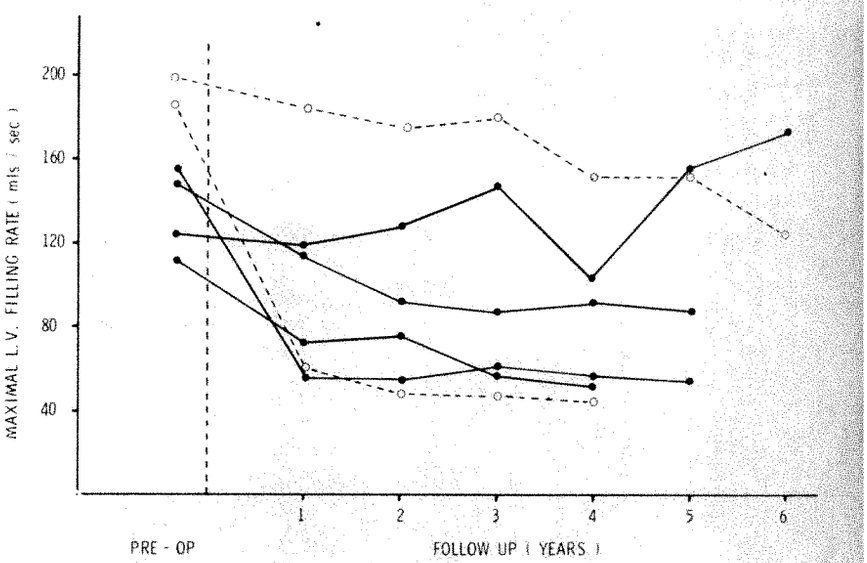

FIGURE 4. Serial changes in maximal left ventricular (L.V.) filling rate in six patients after aortic valve replacement. **Closed circles** = aortic stenosis; **open circles** = aortic regurgitation.

patient with aortic regurgitation initially had a significant decrease in ejection fraction (from 0.62 before operation to 0.53 3 years after valve replacement). However, this value later increased significantly and it is now 0.89 6 years after operation. In the six patients as a group, ejection fraction at the time of latest follow-up ranges between 0.87 and 0.97 (mean 0.92).

Maximal left ventricular filling rate before operation was within the normal range in all four patients with aortic stenosis but was significantly increased in the two patients with aortic regurgitation. One year after valve replacement, three patients including one with aortic regurgitation had a significant decrease in the maximal filling rate with values ranging between 56 and 72 ml/s (Fig. 4). The remaining three patients showed no significant change in filling rate 1 year after operation. However, two of these patients later had a progressive decrease in the maximal filling rate although at the latest follow-up it is within the normal range in both patients. One patient with aortic stenosis showed a marked increase in left ventricular filling rate 5 years after valve replacement in association with the development of significant mitral regurgitation associated with a click and late systolic murmur.

Mitral diastolic closure rate, within normal limits in all patients before operation, showed a progressive decrease in five of the six patients (Fig. 5). At the time of the latest follow-up, three patients including the two with aortic regurgitation showed a marked decrease in rate, with values ranging between 23 and 40 mm/s. In two patients with preoperative aortic stenosis the mitral diastolic closure rate remains at the lower limits of

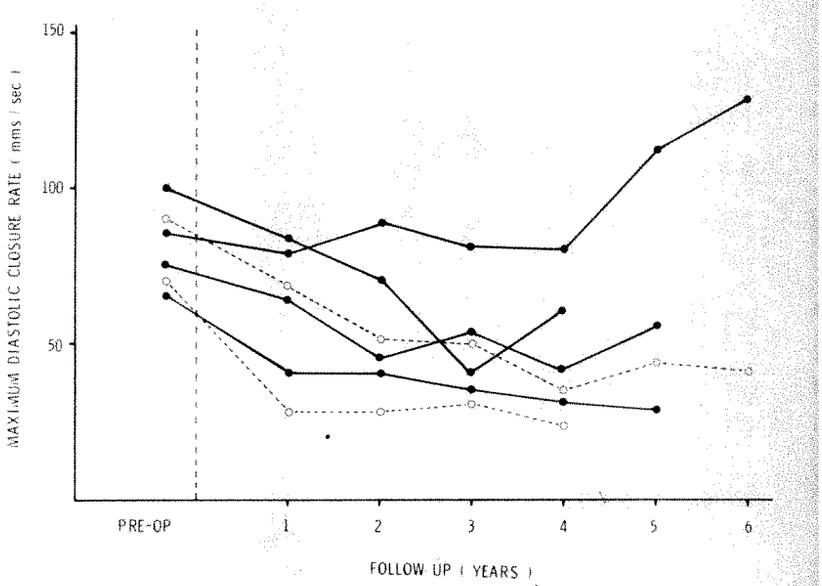

FIGURE 5. Serial changes in rate of mitral diastolic closure in six patients after aortic valve replacement. **Closed circles** = aortic stenosis; **open circles** = aortic regurgitation.

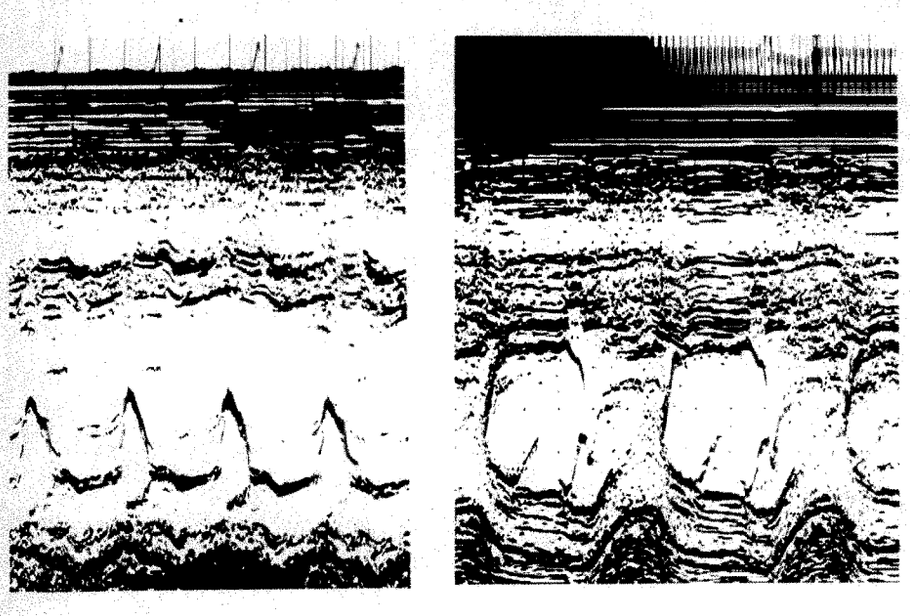

FIGURE 6. Case 3. Echocardiogram of a patient with aortic stenosis before successful aortic valve replacement and 6 years later. PRE-OP and POST-OP = preoperatively and postoperatively, respectively.

normal. In the remaining patient it increased significantly more than 4 years after operation when mitral regurgitation developed.

The preoperative echocardiogram of one patient (Case 3) with aortic stenosis is shown together with that taken 6 years after valve replacement in Figure 6. The preoperative echocardiogram shows no evidence of hypertrophic cardiomyopathy and at cardiac catheterization this patient had a gradient of 120 mm Hg across the aortic valve. The postoperative echocardiogram shows considerable increase in septal thickening with a marked reduction in the mitral diastolic closure rate and prominent systolic anterior movement of the mitral valve.

Postoperative hemodynamic and angiographic findings: All patients were reinvestigated with right and left heart catheterization 2 to 6 years (mean 47 months) after aortic valve replacement. Postoperatively, no patient demonstrated a pressure gradient across the aortic valve either at rest or exercise. However, three patients showed a gradient of 30 to 60 mm Hg across the left ventricular outflow tract at rest. After inhalation of amyl nitrite the gradient across the outflow tract increased in these three patients ranging to 50 to 90 mm Hg (mean 75). In addition, one patient who had shown no gradient at rest had a gradient of 35 mm on provocation with amyl nitrite. The gradient in each case was abolished by the administration of phenylephrine. In

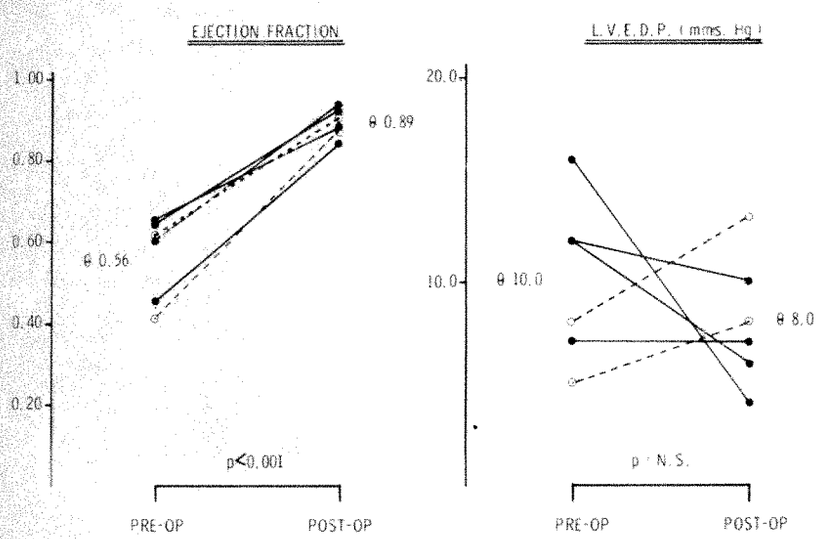

FIGURE 7. Changes in angiographic ejection fraction and left ventricular end-diastolic pressure (L.V.E.D.P.) in six patients after aortic valve replacement. **Closed circles** = aortic stenosis; **open circles** = aortic regurgitation.

two patients a gradient failed to develop despite provocation; these are the two patients who remain entirely free of symptoms.

Ejection fraction calculated with angiography in these patients before operation ranged from 0.41 to 0.65 (mean 0.56) and corresponded very closely to that determined with echocardiography. After valve replacement there was a marked increase in ejection fraction to 0.84 and 0.93 (mean 0.89) (Fig. 7). There was no significant change in left ventricular end-diastolic pressure after operation (Fig. 7), only one patient showing a mild increase. The postoperative left ventricular cineangiogram showed cavity obliteration in systole in all six patients (Fig. 8), although cavity obliteration had not been evident before operation. In concert with this finding, postoperative analysis of left ventricular segmental wall motion showed "supercontractility" in all six patients (Fig. 9).

Discussion

Association between aortic valve stenosis and hypertrophic cardiomyopathy: Such an association is well documented[1–4] and in some patients, particularly those with a congenital bicuspid valve, may be transmitted as an autosomal dominant trait.[11] The diagnosis of hypertrophic cardiomyopathy in the presence of severe aortic valve obstruction presents special difficulties because the valve obstruction tends to mask both the clinical and hemodynamic characteristics of the cardiomyopathy.[4] Improved echocardiographic techniques have allowed identification of these two lesions. However, the absence of a pathognomonic sign of hypertrophic cardiomyopathy gives rise to further diagnostic difficulties.[12] In particular, the presence of asymmetric septal hypertrophy is not diagnostic of hypertrophic cardiomyopathy[13,14] and may occur as a normal variant, particularly in athletes. Similarly, patients with hypertrophic cardiomyopathy may have echocardiographic evidence of concentric left ventricular hypertrophy,[15,16] which may lead to recognition of the cardiomyopathy only at the time of aortic valve replacement or at autopsy.

None of our six patients had evidence of associated hypertrophic cardiomyopathy before operation, as defined by absence of asymmetric septal hypertrophy, systolic anterior motion of the mitral valve, cavity obliteration on angiography or a left ventricular outflow tract gradient. Furthermore, after operation no patient had evidence of abnormal ventricular overload in that none was hypertensive or showed either aortic regurgitation or a transvalve aortic gradient. It might be expected on theoretic grounds that changes suggestive of hypertrophic cardiomyopathy might develop in the early postoperative period when a still markedly hypertrophied ventricle is contracting against a greatly reduced afterload. However, this mechanism is incon-

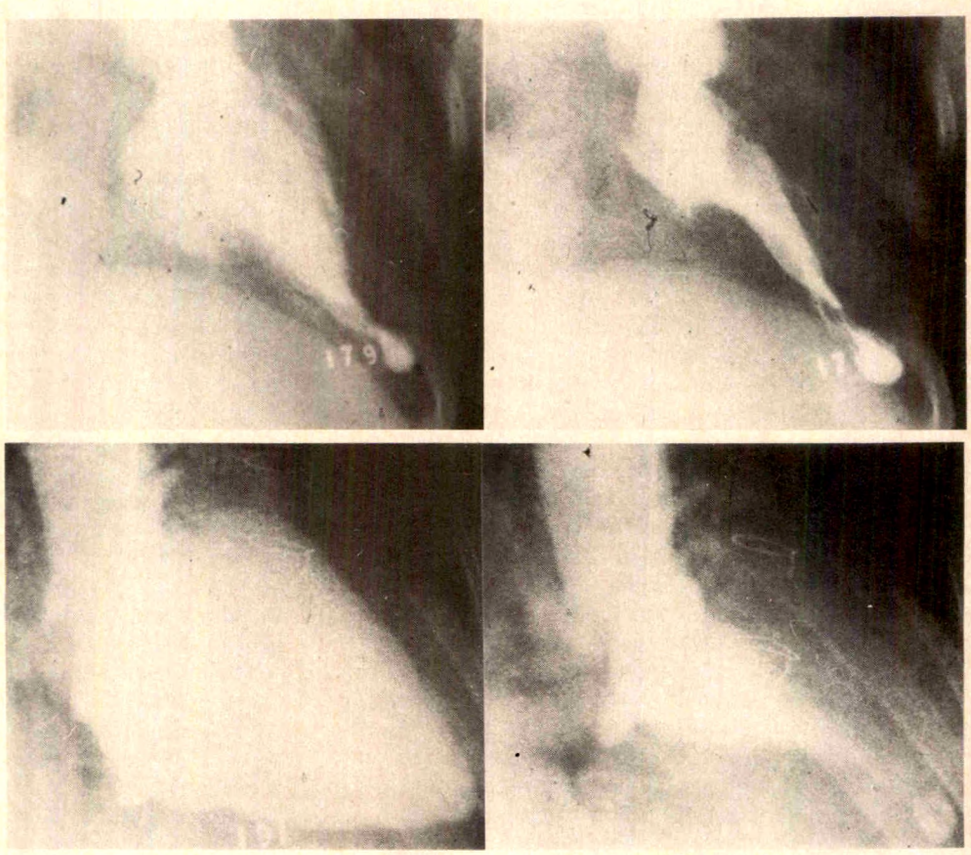

FIGURE 8. Postoperative end-diastolic and end-systolic frames in two patients after aortic valve replacement showing cavity obliteration in systole. **Top,** Case 6 (preoperative aortic regurgitation). **Bottom,** Case 2 (preoperative aortic stenosis).

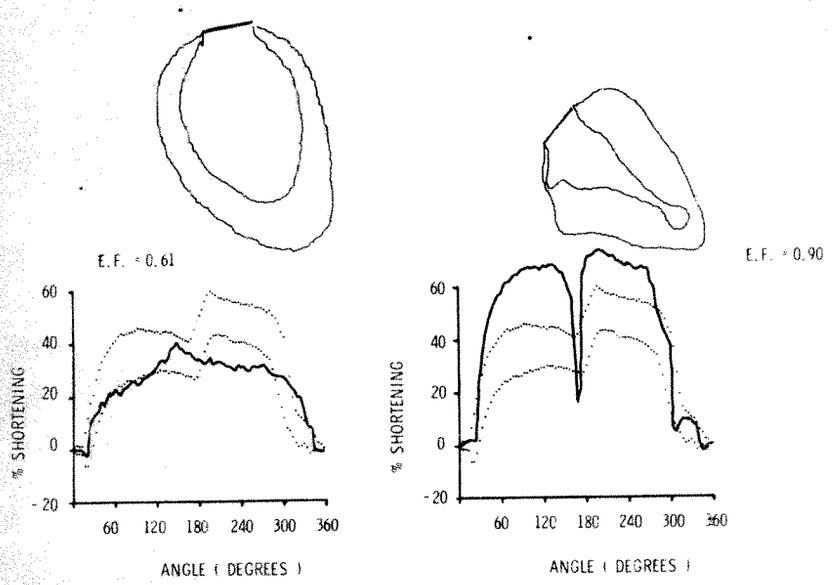

FIGURE 9. Case 5. Computerized radial analysis of segmental wall motion before (**left**) and after (**right**) aortic valve replacement in a patient with preoperative aortic regurgitation. Percent shortening of radials (**vertical axis**) is plotted against angle in degrees around the ventricular perimeter (**horizontal axis**). The **dotted lines** indicate the normal values ± 2 standard deviations obtained in a group of 30 normal patients. The postoperative study shows marked increase in radial shortening well beyond the normal range apart from the site of the apical vent. E.F. = ejection fraction.

sistent with the 3 to 5 year delay in development of cardiomyopathy in our patients.

Progression versus regression of hypertrophy after aortic valve replacement: Regression of left ventricular hypertrophy, as judged both from a decrease in left ventricular mass and from regression of electrocardiographic signs, may be expected in the majority of patients after uncomplicated aortic valve replacement.[17] In a previous series[18] of 53 patients we followed up with serial echocardiography after successful uncomplicated aortic valve replacement, left ventricular mass was decreased significantly to a value within normal limits in 80 percent of patients 2 years after operation. However, in 18 percent of patients, despite an initial decrease in left ventricular mass 1 year after valve replacement, there was no further significant change at 2 years, and in each case the absence of change was associated with the development of significant systemic hypertension. Similarly, there was a significant increase in ejection fraction after valve replacement in the patients in this group with previously impaired left ventricular function. It was significantly increased 1 year after valve replacement and showed a further significant increase at 2 years, but thereafter showed no further change.

These changes are in marked contrast to findings in the six patients described in this report. Despite the successful valve replacement in these six patients, left ventricular mass also showed no significant regression and actually increased progressively with the passage of time. This increase was accompanied by a similar progressive increase both in the ejection fraction and in the septal/posterior wall thickness ratio. This finding implies that these patients had continuing active left ventricular hypertrophy despite successful valve replacement. Three of our six patients showed significant reduction in maximal left ventricular filling rate. Although the latter may be altered by a variety of circumstances, it is possible that in our patients this represents a significant decrease in left ventricular compliance.[19]

Cavity obliteration versus outflow tract obstruction: Although four of our patients demonstrated an intracavity gradient and all six patients manifested obliteration of the left ventricular cavity in systole, it is not clear whether these findings represent true obstruction of the left ventricular outflow tract.[20] Cavity obliteration in systole with or without an associated gradient may be seen in a variety of pressure overload states,[21] particularly in patients with hypertension and aortic stenosis, but may also occur in other hypercontractile cardiac states[22–24] and after acute volume depletion.[25] However, it may be significant that the two patients in our series who remained entirely free of symptoms also failed to show a left ventricular outflow tract gradient either at rest or on provocation.

Mechanism of hypertrophic cardiomyopathy: It seems probable that these six patients represent yet another facet in the spectrum of hypertrophic cardiomyopathy. However, the mechanism that allows continuing left ventricular hypertrophy to occur after successful valve replacement in the absence of abnormal loading conditions is not known. It may be that in a few patients, once the stimulus for myocardial hypertrophy is initiated by the original valve lesion, the response becomes self-perpetuating despite hemodynamic correction and a "malignant" hypertrophy occurs. All of these patients were women, which may imply some form of genetic transmission, although no patient gave a positive family history of sudden death or cardiac disease. Unfortunately, for various reasons, it was not possible to perform echocardiographic studies in the relatives of these patients.

Clinical implication: The true incidence of this late complication of aortic valve replacement is uncertain.

At the present time an additional eight women show suspicious echocardiographic features after aortic valve replacement, namely, systolic anterior motion of the mitral valve together with marginal thickening of the ventricular septum in the absence of hypertension or significant aortic regurgitation. All these patients are now asymptomatic and it remains to be seen whether they will eventually have the full manifestations of hypertrophic cardiomyopathy. The failure of others to report this late complication may be related to follow-up methods. At our institution we attempt to reevaluate all patients undergoing valve replacement at annual intervals with echocardiography and as part of the clinical examination. Undoubtedly, more cases would come to light if such reevaluation were a widespread practice.

Hemodynamic Evaluation of Patients With Combined Mitral and Aortic Prostheses

WILLIAM A. BAXLEY, MD, FACC
BENIGNO SOTO, MD, FACC

Birmingham, Alabama

Complete hemodynamic evaluation of patients with combined aortic and mitral mechanical valve prostheses presents a difficult technical problem. Yet such patients with cardiac symptoms postoperatively often require this evaluation to determine the diagnosis and the advisability of reoperation. A 4 year experience with 22 patients requiring such evaluation is reviewed. Eight patients (36 percent) required reoperation for malfunction of the prosthesis. Four (18 percent) had major complications of the cardiac catheterization study, but no fatalities or residual permanent defects resulted. In 17 cases transthoracic left ventricular needle entry was used. A standardized procedure of this type for both pressure measurement and angiographic studies has evolved, providing reasonable efficiency and a relative degree of safety. The patient is positioned in the right anterior oblique position for optimal needle entry into the left ventricular apex and angiographic visualization of mitral prosthetic incompetence and the myocardial contractile pattern. A 16 gauge needle with side holes but no end hole allows ventriculography to be performed after chamber entry using the prostheses as reference points under fluoroscopic guidance. Retrograde catheterization of the aortic prosthesis, transseptal left atrial catheterization with anterograde crossing of the mitral prosthesis and transapical pressure measurement with a smaller needle, combined with quantitative left atrial angiography, are alternative choices for study.

Most therapeutic advances in medicine bring new diagnostic challenges. Thus, cardiac evaluation of patients who are symptomatic in spite of valve replacement is often technically more difficult than the original preoperative evaluation.[1,2] This is particularly true in patients with mechanical prostheses in both the aortic and mitral positions. Murmurs and other physical signs are usually not sufficiently specific for a quantitative surgical diagnosis. Noninvasive techniques such as echocardiography, phonocardiography and nuclear imaging are helpful but often not specific; they may suggest poor myocardial performance but do not rule out coexistent malfunction of the prosthesis. Indeed, the expected "normal" left ventricular responses to acute aortic prosthetic stenosis are dilatation and a decrease in ejection fraction,[3] which may mimic isolated poor ventricular function as assessed with noninvasive studies.

Fluoroscopically, restricted motion of the prosthetic poppet or flap, not explained by poor ventricular performance, is an indication of stenosis of the prosthesis and the need for operation.[4] Also, excessive swinging of the ring support is a sign of detachment of the prosthesis.[5] Aortography alone may suffice, revealing severe insufficiency of the aortic prosthesis or evidence of a clotted valve. However, malfunction of the prosthesis may be a treacherous and rapidly progressive condition; the decision to repeat valve surgery often requires complete cardiac

catheterization study including left ventricular entry for evaluation of the prosthesis as well as determination of myocardial and coronary arterial status. Such study should only be performed in centers experienced in these unique problems. However, in light of the growing number of patients with double valve prostheses, it is important for all physicians active in cardiology to be familiar with the issues involved.

Mechanical prostheses in the aortic position may be crossed with a catheter[6]; however, this maneuver is often difficult or impossible to accomplish. In addition, there is the risk of embolization of a clot from a stenosed mechanical prosthesis as it is traumatized by a catheter. Escape of the poppet from some valves is a recognized catastrophic event[7] and can be a complication of attempted retrograde cardiac catheterization of an aortic valve prosthesis. Furthermore, the catheter across the prosthesis will result in valve regurgitation that may preclude accurate baseline hemodynamic measurements. For these reasons, we have generally avoided retrograde left ventricular cardiac catheterization in patients with a mechanical aortic prosthesis.

Even normally functioning prostheses often have significant pressure gradients.[8] To compound further the diagnostic problem in evaluating the gradients, cardiac output may be reduced because of heart failure or it may be high in association with hemolytic anemia. Thus, a small gradient may be present across a stenosed prosthesis or a high gradient across a normally functioning one. Calculation of a valve orifice cross-sectional area may not yield a clear diagnosis because the area may change with heart rate as a result of inertia of the poppet or flap.

In view of these problems and others such as management of anticoagulation during cardiac catheterization and because there have been few published reports on the subject, we reviewed our experience in evaluating symptomatic patients with mechanical double valve prostheses. A particular aim was to develop a safe and effective transthoracic approach to measurement of left ventricular pressure and performance with angiography. Although diagnostic transthoracic left ventricular entry is a relatively old procedure,[9,10] it has never been widely utilized and in particular it has not been standardized for the study of postoperative patients with double prosthetic values.

Methods

Patients: The data on all adults with double valve mechanical prostheses (mitral plus aortic) who had postoperative cardiac catheterization after 1972 were reviewed. Only patients whose study was performed with left ventricular entry by needle or catheter were included. No patients with tissue valves were considered. All were studied because of persistent or recurrent postoperative cardiac symptoms and were evaluated for possible reoperation. The techniques utilized in left ventricular entry were analyzed retrospectively to determine the most effective method.

Twenty-two patients met the selection criteria (Table I). All had mechanical prostheses of the Starr-Edwards, Braunwald-Cutter or Bjork-Shiley variety in both the mitral and aortic positions, and one patient had in addition, a tricuspid valve prosthesis. There were 14 men and 8 women aged 21 to 63 years (average 43). Valve replacement had been performed 1 to 91 months previously (mean 37 months). Study was undertaken because of suspected malfunction of the prosthesis causing symptoms of heart failure, angina pectoris or stroke.

Cardiac catheterization procedures: Seventeen patients had transthoracic left ventricular entry, 3 had retrograde left ventricular catheterization with a Sones coronary catheter across the aortic prosthesis and 1 had anterograde entry into the left ventricle through a mitral prosthesis with a transseptal left atrial catheter. Two of the patients with transthoracic entry also had transseptal left atrial catheterization. All but one had retrograde aortic catheterization. Eleven patients had left heart angiography; in eight this procedure was performed with use of the transthoracic needle, in two by way of transseptal left atrial angiography, and in one with use of the retrograde approach across the aortic prosthesis into the left ventricle. Nine patients had aortic root cineangiography and seven had coronary angiography.

Management of anticoagulation therapy: All patients had been having long-term therapy with Coumadin before this study. In most patients use of this drug was discontinued or continued in reduced dosage for several days before cardiac catheterization and resumed after the study. In one patient intravenous heparin was administered for several days and then discontinued 8 hours before the study. No heparin was given during the cardiac catheterizations. Prothrombin times during the 24 hours before the study were 0 to 14.1 seconds longer than the control times (mean 3.8 seconds) or 20 to 100 percent activity (mean 52 percent).

Results

Complications of cardiac catheterization: Significant nonfatal complications of the cardiac catheterization study occurred in 4 of the 22 patients (18 percent). The most serious complication occurred in a severely ill patient taken urgently the day after study to surgery because of malfunction of the prosthesis. He had left ventricular enlargement with good ventricular function. No complication was evident during or immediately after the study. However, early postoperatively, pericardial tamponade occurred and at reexploration myocardial suturing was required because of bleeding through the site of the left ventricular apical puncture. Heparinization and operative manipulation during the open heart procedure apparently contributed to the occurrence of bleeding at the site of the previous day's puncture. Two other patients required observation in the coronary care unit for pleuritic chest pain after transapical study. One of these patients had an associated pleuritic rub, and one had slight pleural effusion on X ray film 3 days after study; both conditions resolved. One other patient had transient aphasia, probably due to cerebral embolus, after combined retrograde aortic prosthetic catheterization and transseptal left atrial catheterization with left atrial angiography. Two other patients had minor complications characterized by transient moderately severe pleuritic chest pain after transapical withdrawal of the needle; both required narcotic drugs for relief.

Catheterization diagnoses: Results of the 22 cardiac catheterizations revealed a variety of cardiac diagnoses. Seven patients had poor ventricular function with good

function of the prosthesis, five had mitral prosthetic regurgitation, three had aortic stenosis, three had mitral stenosis and four had normal findings. Eight (36 percent) required reoperation for malfunction of the prosthetic valve.

Proposed technique for transthoracic left ventricular apical entry: Analysis of the methods of left ventricular entry by a transapical percutaneous needle suggested the following protocal for safe, effective use of this technique.

A. *Initially, right heart and retrograde aortic catheterization are performed under optimal patient sedation.* The right heart catheter should remain near the pulmonary "wedge" position. Both catheters should be used to monitor pressures and be available for quick recording of transprosthetic pressure gradients. Before left ventricular catheterization, test doses of contrast dye should be given intravenously to minimize the chances of reaction later.

B. *Left ventricular transapical needle entry is performed.* Our initial studies were made with either a no. 18 or a no. 20 spinal type needle. Recently we have used a no. 16 thin-wall steel needle that has side holes but no end hole. This needle has an obturator to add strength during entry and was designed to facilitate left ventriculography. *The sequence of left ventricular entry is as follows:*

1. *The patient is comfortably placed partially on his left side* with the vertically mounted fluorocine unit in a right anterior oblique projection. Adjustments should be made to bring the mitral valve prosthesis into profile for angiographic evaluation of regurgitation. This is most easily done with a "Z arm" or other rotating fluoroscopic unit. This position also brings the long axis of the left ventricle relatively perpendicular to the X ray beam both for optimal visualization of ventricular contractions and to present the easiest target for entry of the needle at the cardiac apex. Furthermore, the left ventricular apex can be most easily felt against the chest wall in this position. Pressure transducers, connecting tubing, contrast injectors, recorders and auxillary equipment should all be in readiness for quick data acquisition (Fig. 1).

2. *The apex impulse is palpated and the entry site anesthetized.* This site should be 1 inch (2.5 cm) or so from the center of the apical impulse and located just outside the apex fluoroscopically. Generally, this is one interspace below and outside the point of maximal impulse. A slight nick is made in the skin. The transthoracic needle is introduced subcutaneously. The needle preferred is 16 gauge, 6 inches (15.24 cm) long, thin-walled with a sharp tip and side holes only (no end hole, so that no destructive jet of contrast material will ensue during angiography), with a blunt obturator for added

TABLE I

Individual Patient Data

Case no.	Age (yr) & Sex	Type of Prosthesis	Months Postop	Approach	Angiographic Study	Cardiac Diagnosis	Complications	Reoperation

22	22M	BS	3	TA	LV	MR	0	Yes

* Patient 16 had three prostheses—mitral, aortic and tricuspid.

Ao = aortogram; AS = aortic stenosis; BC = Braunwald-Cutter; BS = Bjork-Shiley; CAD = coronary artery disease; CAG = coronary arteriograms; LA = left atrial angiogram; LV = left ventriculogram; ↓LVFx = decreased left ventricular function; MR = mitral regurgitation; MS = mitral stenosis; Postop = postoperative; R = retrograde; RA = right atrial angiogram; SE = Starr-Edwards; TA = transapical; TS = transseptal; WNL = findings within normal limits.

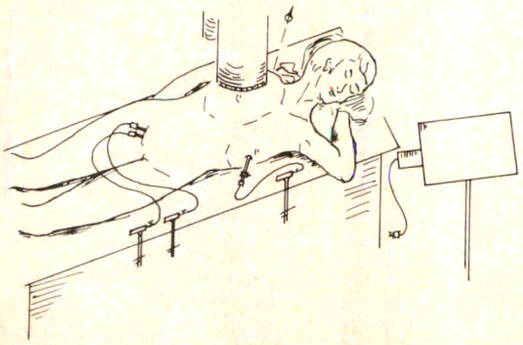

FIGURE 1. Schematic drawing of transapical left ventricular puncture. The patient is positioned comfortably partially on his left side so that the mitral prosthesis is in profile through the vertically mounted cine-fluoroscopic unit. Pressure is monitored through arterial and "wedge" position catheters, and the power contrast injector prepared for left ventriculography. The apical needle is then introduced under fluorscopic control, toward the right scapula (**arrow**).

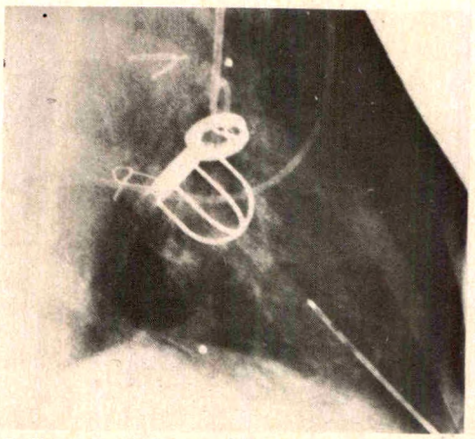

FIGURE 2. Fluoroscopic image of the correct position of the apical needle in the left ventricular chamber. Note the right anterior oblique projection, the mitral prosthesis (**lower valve**) in profile and needle entry near the apex but pointed toward the valves along the long axis of the ventricle.

stiffness during entry. A sliding "stop" should be affixed.

3. *At this time, cardiac output is measured* for use in calculating valve areas and quantitating regurgitant flow by angiography. This value, as well as that of heart rate, may be higher than earlier baseline values because of patient anxiety.

4. *The needle is advanced in a straight line, in the horizontal plane* and aimed fluoroscopically directly at the aortic prosthesis, which represents the base of the heart. In the vertical plane it is deflected to aim posteriorly toward the right scapula. The cardiac pulsation will be encountered. Premature contractions may be noted. The needle is advanced further in increments of 1/2 cm, and the obturator removed after each advancement to check for blood. Entrance into the cavity is heralded by pulsatile blood effluent. The stop is tightened against the skin to steady the needle, and pressure is measured to verify the position (if necessary, blood oximetry may also be performed). While the needle is further steadied by a hemostat, simultaneous pressures in left ventricle-pulmonary wedge positions, followed by left ventricle-aortic root positions are recorded (Fig. 2).

5. *A cautious test injection of contrast material is made through the needle.* Care should be exercised that all side holes are in the ventricular cavity; placement of one or more holes in the myocardial wall will later result in partial intramyocardial injection.

6. *A power injection is made* with 36 to 44 ml of contrast medium at a rate of 12 to 14 ml/s during quiet respiration. "A deep inspiration" during filming or at any other time during needle use is contraindicated. Figures 3 and 4 are examples of left ventriculograms.

7. *The needle is withdrawn,* the patient carefully monitored in the laboratory for 30 minutes and anal-

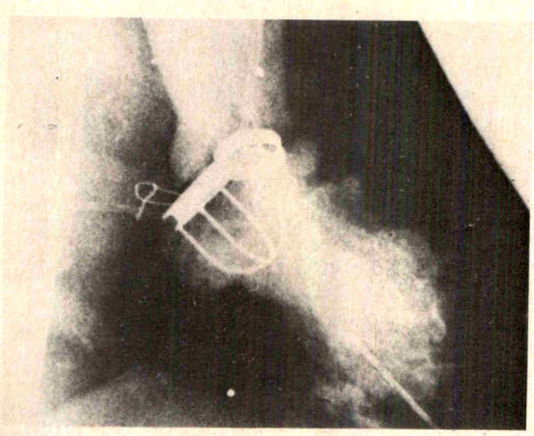

FIGURE 3. Systolic frame from a left cineventriculogram with injection through the apical needle. The mitral prosthesis is competent, and there is no regurgitation of contrast medium into the left atrium.

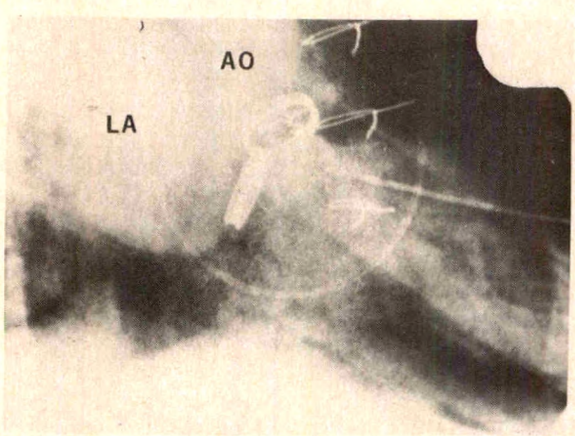

FIGURE 4. Frame from a left cineventriculogram (right anterior oblique projection) in a patient with severe incompetence of a Bjork-Shiley mitral prosthesis (**lower valve**). Note the dense reflux opacification of the left atrium (LA) below the aorta (AO). In this example, the needle has erroneously been introduced too high through the free left ventricular wall rather than through the apex.

gesia for pleuritic chest pain administered if needed. The patient is observed closely overnight for complications.

Discussion

Problems in diagnostic evaluation: Experience with these 22 symptomatic patients with double mechanical valve prostheses has revealed some important features concerning their diagnostic evaluation. First, complete hemodynamic evaluation is often necessary, as evidenced by the eight patients (36 percent) who required reoperation. Such study allows one to make the decision to reoperate on the same rational quantitative basis as that used before the initial operation. The mortality rate of reoperation has been shown to be in the acceptable range.[11] Second, the studies are somewhat difficult but not prohibitively so, although they carry a greater risk than is generally attendant in preoperative cardiac catheterization for valvular heart disease in adults. Although there were no fatal or permanent residual sequelae in our study, four patients (18 percent) had significant complications attributable to the diagnostic procedure. This rate is similar to the 24 percent complication rate for transthoracic left ventricular study noted by Morton et al.[2]

Proposed plan of diagnostic evaluation: During the last several years we have developed the following plan of evaluation of such patients in accord with the lessons and techniques learned from this series.

A. *Initial communication among the cardiologist, surgeon, radiologist and the patient himself:* This is important in order to determine if the patient is indeed a candidate for reoperation, and, if so, under what conditions, and the specific data required. It is necessary to individualize the planned study for each patient, owing to the multiplicity of disorders present in this group.

B. *Anticoagulant management:* Ideally, anticoagulation should not be so great as to enhance complications of bleeding during catheterization, yet should be maintained to the extent that clotting on a potentially malfunctioning prosthesis is retarded. The safest procedure appears to be discontinuation of oral anticoagulant therapy 3 to 4 days before study and maintenance with parenteral heparin until shortly before study. An alternative procedure is to discontinue oral anticoagulant therapy 1 to 2 days before study and to perform the investigation with the blood in the partially anticoagulated state. Full anticoagulation can then be restarted the day after study. Morton et al.[2] suggested that study with partial anticoagulation is the most advantageous procedure.

C. *Catheterization procedure:* Review of the procedures utilized for left ventricular entry suggests that transapical needle entry is the procedure of choice in most patients with mechanical prostheses in both the mitral and aortic positions. Although this procedure does have risk, at our institution the study is performed by the cardiologist with consultation of the radiologist without surgical stand-by. Several factors make such study easier in this group of patients than in patients who have not been operated on: (1) The pericardium is generally adherent to the epicardium because of previous scarring from the operation. Thus, there is little chance that pericardial tamponade will occur after the study. (2) The prostheses, particularly the aortic, make excellent fluoroscopic landmarks for guiding the needle entry. (3) The spiral arrangement of the muscular layers of the myocardium is a favorable anatomic arrangement to prevent bleeding from the left ventricular chamber. This is particularly true in the hypertrophied heart, which is generally found in such patients. Furthermore, the coronary arteries, a source of potential bleeding, are smallest in size at the apex where needle entry occurs.

Prevention of complications of procedure: Potential problems that may result from transthoracic left ventricular entry include pneumothorax, coronary arterial laceration, pericardial tamponade or pleural effusion, bleeding or hematoma formation, myocardial injury from angiography, arrhythmias and embolization. Two patients in our series had pleural effusions with chest pain, presumably due to bleeding from intercostal vessels. In the series of Bjork et al.,[10] 142 left ventricular punctures were reported. Complications included frequent premature ventricular complexes in one patient, right ventricular entry in two, and ventricular fibrillation requiring resuscitation in one patient. The most difficulties are encountered in men with large "barrel chests" and no cardiac enlargement, such as might result from an original preoperative combination of aortic stenosis and mitral stenosis. An alternative approach to the study of such patients would be attempted retrograde catheterization of the left ventricle, or transseptal catheterization with anterograde mitral crossing. Both procedures were successful in several patients in our series. Also, a more cautious approach is the use of a thin needle such as a 20 gauge spinal type, for percutaneous measurement of pressure only. In such cases, angiography can be performed with left atrial injection through a transseptal catheter. Regurgitation can then be assessed by quantitative angiography with calculation of ventricular volumes from the films.[12] The presence of the valve prostheses, plus a lateral view fluoroscopic tube, generally enhances the ease of transseptal cardiac catheterization in this type of patient.

One patient in our series had triple valve prostheses. In such patients the pulmonary wedge pressure can be obtained only by passing a catheter through the tricuspid valve prosthesis. We have performed this maneuver without incident in several patients, utilizing a Swan-Ganz catheter. However, an alternative approach is to combine transapical and transseptal approaches. In addition to being useful for the left atrial pressure measurement, the transseptal catheter can be wedged into a pulmonary vein for recording of the pulmonary arterial pressure for a more complete hemodynamic evaluation.

Coronary Hemodynamic Effects of Ergonovine Maleate in Human Subjects

ARTHUR E. ORLICK, MD, FACC
DONALD R. RICCI, MD, FRCP(C), FACC*
PAUL R. CIPRIANO, MD
DIANA F. GUTHANER, MD

Stanford, California

The coronary hemodynamic effects of ergonovine maleate were examined in 15 patients with a chest pain syndrome not thought to be variant angina. Ergonovine was given intravenously in sequential doses of 0.05, 0.1 and 0.25 mg while measurements were made of systemic hemodynamic variables, coronary sinus blood flow and coronary arteriovenous oxygen difference at intervals during the protocol. Coronary arterial diameters were measured from the 35 mm cineangiogram. Despite an increase in myocardial metabolic demand, as estimated with the heart-rate-blood pressure product, there was no apparent increase in coronary vascular resistance. In addition, there was a significant widening of the coronary arteriovenous oxygen difference in five of the seven patients in whom it could be measured. However, neither chest pain nor ischemic electrocardiographic changes were evoked. Although ergonovine also produced a diminution in epicardial coronary arterial diameters, this effect was not sufficient to explain the absence of appropriate coronary vasodilation. These results suggest that ergonovine may limit the normal vasodilatory response of the arteriolar bed to increases in myocardial metabolic demand.

Interest in the syndrome of variant angina has grown since the discovery that various pharmacologic agents are capable of reproducing its clinical features by provoking coronary arterial spasm.[1–6] Ergonovine maleate is one such agent. Given intravenously, it is very effective in precipitating spasm in patients with variant angina but not in patients with atypical forms of chest pain.[4,5] In spite of its increasing use in cardiac catheterization laboratories, its hemodynamic effects on the coronary circulation have not been adequately investigated.

In this report we examine the coronary and systemic hemodynamic effects of ergonovine maleate administered to patients with atypical nonvariant forms of chest pain. Our results suggest that ergonovine maleate exerts its vasoconstrictive effect not only on large epicardial coronary arteries, but also on the smaller autoregulatory arterioles.

Methods

Patients: We studied 15 patients, 10 men and 5 women, ranging in age from 25 to 59 years, at the time of clinical evaluation for chest pain. All patients had an atypical nonexertional form of chest pain that occurred at odd times during the day and night and was not consistently relieved with nitroglycerin. During episodes of chest pain no patient had documented S-T segment elevation or depression or changes in blood pressure or heart rate. All patients gave informed consent in accordance with the Stanford University Committee on the Use of Human Subjects in Research. No complications occurred during this investigation.

Hemodynamic and angiographic studies: Left ventriculography and coronary angiography were performed in all patients using the Judkins technique.[7] We measured coronary sinus blood flow with the thermodilution technique of Ganz et al.[8] The thermodilution catheter (Wilton Webster Laboratories, Alta-

dena, California) was inserted into the coronary sinus through a left antecubital vein with the tip positioned at least 5 cm from the coronary sinus ostium to avoid right atrial contamination.[9] The catheter was firmly secured at the venous entry site and precautions were taken to ensure a stable catheter position throughout the study. In our laboratory the reproducibility of this technique as determined by 26 duplicate measurements in 18 patients is 4 ± 8.2 percent (mean ± standard deviation). Arterial pressure was measured through a Judkins coronary arterial catheter positioned at the coronary arterial ostium using a Statham P23Db pressure transducer (Statham Instruments, Inc., Oxnard, California) connected to a Hewlett-Packard optical recording system. All coronary sinus flow measurements were made with the coronary arterial catheter in this position. Arterial and coronary sinus oxygen content levels were measured in seven patients using the method of Gordy and Drabkin.[10] A 12 lead electrocardiogram was recorded intermittently throughout the drug protocol.

At the completion of routine angiographic studies, control coronary sinus blood flow measurements were obtained. Next 0.4 mg of ergonovine maleate was administered in three doses of 0.05, 0.1 and 0.25 mg at 3 minute intervals while a 12 lead electrocardiogram and arterial pressure were recorded at 1 minute intervals. At the end of a 3 minute period coronary sinus blood flow was measured and the left coronary artery visualized with use of selective injection of 5 to 8 ml of meglumine and sodium diatrizoate (Renografin® 76). In seven patients, arterial and coronary sinus blood samples were obtained simultaneously for determination of oxygen content before each flow measurement.

Coronary vascular resistance was calculated as the quotient of mean arterial pressure and coronary sinus blood flow. Myocardial metabolic demand was estimated from the product of systolic arterial pressure and heart rate.[11] The diameter of the left anterior descending and circumflex coronary arteries was measured with calipers from the cineangiogram obtained before and after each dose of ergonovine, as previously described.[12] The largest reduction in diameter was used for analytical purposes.

Statistical analysis: Student's *t* test for paired data with equal variance was used for statistical analysis.

Results

Coronary angiographic findings: coronary arterial diameter: Table I summarizes the angiographic findings and the changes in coronary arterial diameters produced with ergonovine maleate. No patient had angiographic evidence of mitral valve prolapse. A normal left ventricular contraction pattern was noted in 14 of the 15 patients. Patient 5 had a contraction abnormality of the anterolateral and apical walls. He had no historical or electrocardiographic evidence of a prior myocardial infarction to explain the hypokinesia. Patient 1 had a significant occlusion (greater than 50 percent reduction of luminal diameter), of the right coronary artery, and four patients had significant lesions involving the left anterior descending or major diagonal branch. All other patients had either normal arteries or insignificant coronary occlusive disease (less than 50% stenosis).

In response to ergonovine there was a 22.5 percent reduction in the diameter of the left anterior descending coronary artery (from 3.1 to 2.4 mm, $p < 0.001$) and a 17.7 percent decrease in diameter of the left circumflex coronary artery (from 3.2 to 2.6, $p < 0.01$). The coronary arterial narrowing occurred diffusely throughout the entire length of the vessels. Neither chest pain nor electrocardiographic changes were associated with this reduction in coronary arterial diameter.

Hemodynamic data: Table II presents the hemodynamic data in all patients before and after ergonovine. There was an increase in mean arterial pressure (from 104 to 120 mm Hg, $p < 0.001$) and a 26 percent increment in heart rate-pressure product (from 10.54 to 12.95

CSBF = coronary sinus blood flow; CVR = coronary vascular resistance; $\Delta a\text{-}vO_2$ = arteriovenous oxygen difference; MAP = mean arterial pressure; NS = not significant; SAP·HR = systolic arterial blood pressure-heart rate product; SEM = standard error of the mean.

units, $p < 0.05$). There was also a slight but insignificant rise in heart rate (from 77 to 79 beats/min). The changes in coronary hemodynamics in response to ergonovine demonstrated more variability than the alterations in the systemic hemodynamics. Increases in coronary sinus flow were noted in 11 of 14 patients. Patients 3, 12 and 15 had significant decreases in coronary sinus flow, whereas Patient 14 had essentially no change in measured flow. Patients 3 and 15 also had significant left coronary arterial lesions. In the group as a whole, coronary sinus flow increased (from 124 to 155 ml/min, $p < 0.05$). Calculated coronary vascular resistance remained essentially unchanged after ergonovine administration (0.90 versus 0.92 mm Hg/ml per min), although considerable variability was noted.

Of particular interest were the changes in the coronary arteriovenous oxygen difference. Five patients (Cases 8, 9, 12, 13 and 15) demonstrated significant widening of the coronary arteriovenous oxygen difference, but in two patients (Cases 4 and 7) there was essentially no change. These two patients also had the largest increments in coronary sinus flow of the seven patients in whom coronary arteriovenous oxygen differences could be measured. The reason for the marked increase in coronary sinus flow in Patient 7, despite significant stenosis of the left anterior descending coronary artery is not clear. Patient 15, who had the most severe left coronary artery disease, had the largest increment in coronary arteriovenous oxygen difference and the largest proportionate decrease in coronary sinus flow. The mean group value for coronary arteriovenous oxygen difference increased (from 11.31 to 12.93 vol percent, $p < 0.05$).

Figure 1 graphically compares the changes in coronary arteriovenous oxygen difference and coronary vascular resistance in the seven patients whose coronary sinus blood could be obtained for oxygen content determination. Figure 2 compares and summarizes the changes in heart rate-pressure product and coronary vascular resistance produced by ergonovine.

Discussion

We examined the coronary and systemic hemodynamic effects of ergonovine maleate in a group of patients with atypical chest pain, in whom ergonovine did not provoke coronary spasm, in order to understand the normal pharmacologic effects of this agent on the coronary and systemic circulations. The observed increase in arterial pressure and modest reduction in coronary arterial diameters were similar to the data reported by Curry et al.[13] and Goldberg et al.[14] These effects are presumably related to the interaction of ergonovine, a known alpha agonist, with peripheral and coronary alpha adrenergic receptors.

Coronary hemodynamic effects of ergonovine: These effects are of particular interest in that an understanding of the pharmacologic effect of ergonovine might provide insight into its action in patients with variant angina. The data suggest that, in addition to its other effects, ergonovine effectively limits the ability of the myocardial arteriolar bed to vasodilate in response to an augmented myocardial metabolic requirement. This conclusion is supported by several observations. We noted a 26 percent rise in heart rate-pressure product in response to ergonovine. This rise, coupled with the previously noted increase in left ventricular end-diastolic pressure,[13] would effectively augment myocardial oxygen demand. The physiologic response of the coronary circulation in this circumstance would be vasodilation, in order to match myocardial oxygen delivery to the increased demand. Thus, the unchanged calculated coronary vascular resistance in our patients is surprising and probably reflects the limitation in arteriolar autoregulatory capacity pro-

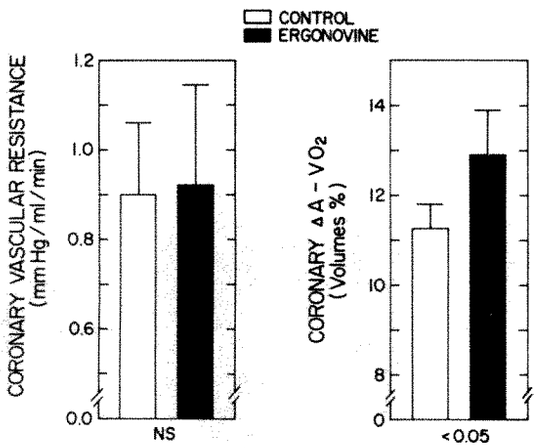

FIGURE 1. Comparison of the changes in coronary vascular resistance and coronary arteriovenous oxygen difference (ΔA-VO_2) produced by ergonovine maleate in seven patients. Note the widening of the coronary arteriovenous oxygen difference in the presence of no apparent change in coronary vascular resistance. NS = not significant.

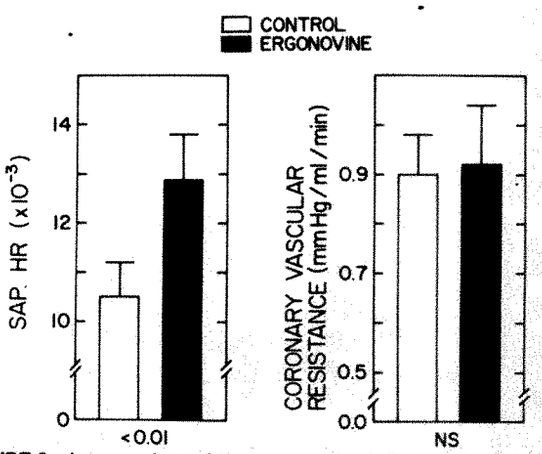

FIGURE 2. A comparison of changes in myocardial metabolic demand as estimated by heart rate-systolic arterial pressure product (SAP·HR) and coronary vascular resistance produced by ergonovine. Although there was a significant rise in rate-pressure product, there was no apparent decrease in coronary vascular resistance as would ordinarily be expected with an increased demand.

duced by ergonovine. An additional finding supporting this concept is the 14 percent widening of the coronary arteriovenous oxygen difference. If the increase in coronary flow was adequate to meet the increase in myocardial oxygen demand then an increase in oxygen extraction should not be necessary. The increased myocardial oxygen extraction in our patients further supports the view of limited autoregulatory capacity. This limitation was not sufficient to produce myocardial ischemia, as evidenced by the absence of both chest pain and ischemic ST-T changes in the electrocardiogram.

Curry et al.[13] also noted insignificant changes in myocardial lactate extraction in their patients with nonvariant angina, again suggesting that the limitation in vasodilating ability of the arteriolar bed was not severe enough to produce myocardial ischemia.

Our results are similar to those recently reported by Goldberg et al.[14] in their patients with atypical chest pain. Although the changes in systemic and coronary hemodynamics were similar to those manifested by our patients, coronary arteriovenous oxygen difference was unchanged in five patients in whom the measurement could be made. The reason for the discrepancy between the two studies in myocardial oxygen extraction data is not entirely clear. One possibility is that nitroglycerin, which was administered to their patients before the study, in some way blunted the effect of ergonovine; our patients did not receive nitrates.

Although our patients had a 20 percent reduction in epicardial coronary arterial diameter, limitation in resting coronary flow is usually seen only with decreases in luminal diameter of more than 85 percent.[15] Thus we would not expect this modest increase in epicardial coronary resistance to exhaust the myocardial autoregulatory reserve. In addition, the narrowing that occurred was not localized at the sites of lesions that would tend to make nonsignificant lesions hemodynamically significant.

Clinical implications: The concept of a limitation in vasodilatory capacity in response to an increased myocardial oxygen requirement is not new. Mohrman and Feigl[16] in an animal preparation recently showed that myocardial oxygen delivery in response to augmented myocardial metabolic requirement can be enhanced by approximately 30 percent with alpha adrenergic blockade. Although the mechanism responsible for ergonovine's ability to limit myocardial oxygen delivery may be different from that reported in animals, the end result would appear to be similar. This effect may be important in producing chest pain and myocardial ischemia in patients with nonvariant angina and significant coronary occlusion who are given ergonovine. It may also explain the reported large incidence of ergonovine-induced chest pain and ischemic electrocardiographic changes among patients with classic exertional angina.[17,18]

Acknowledgment

We express our sincere appreciation to Diana Windsor for excellent secretarial assistance.

How oral nitroglycerin therapy works

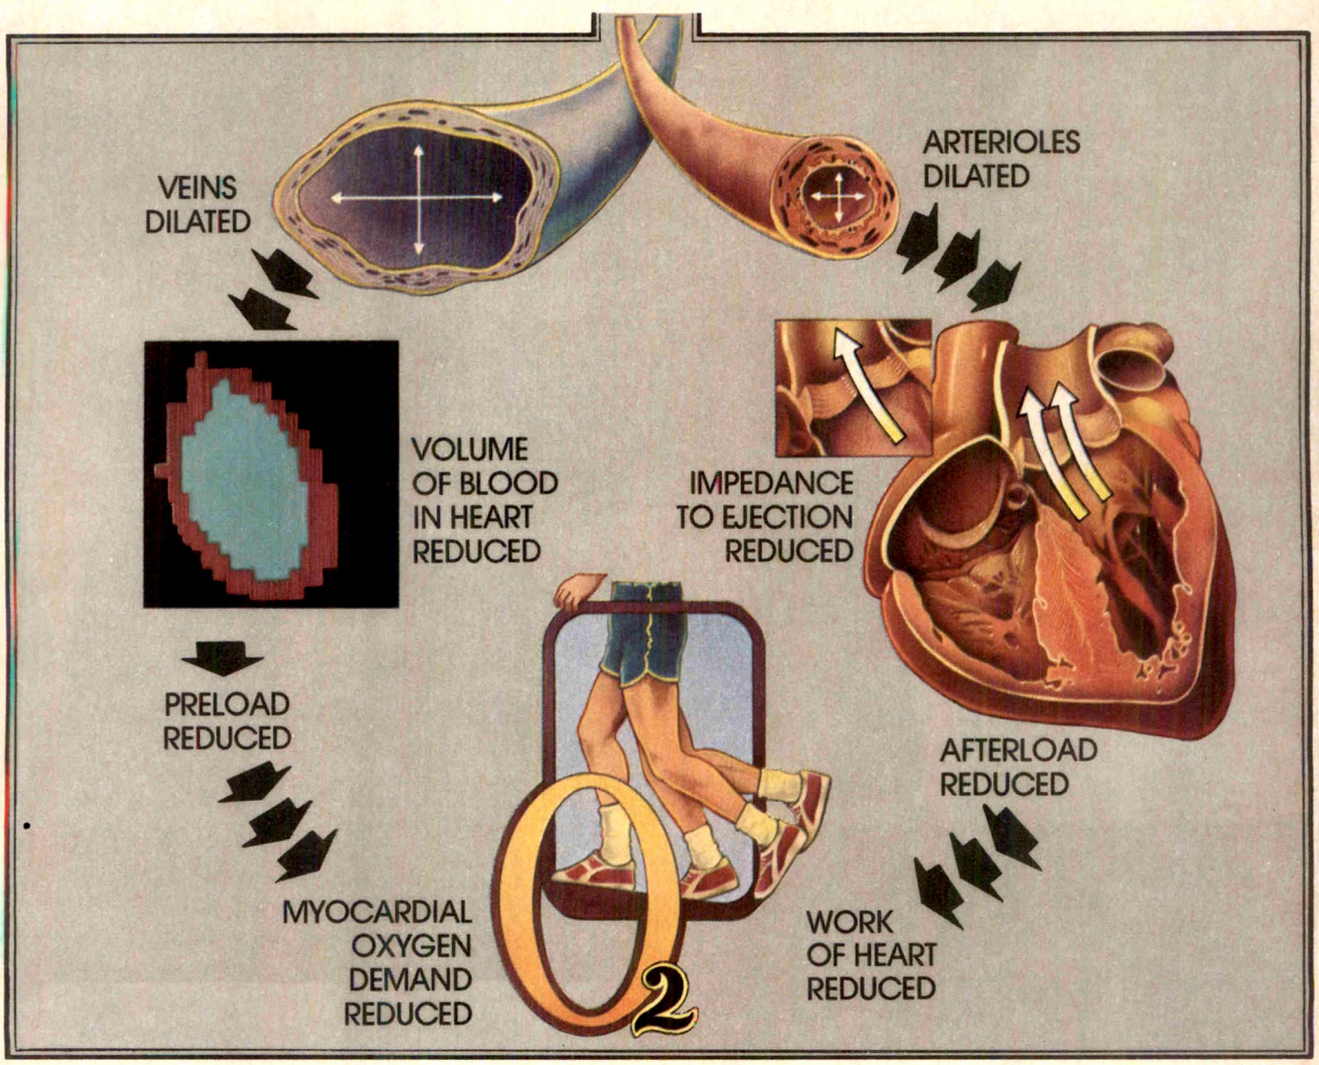
"After ONTG [controlled-release oral nitroglycerin, 6.5 mg to 19.5 mg] ingestion left ventricular filling pressure (LVFP) diminished in 20 min....declined maximally within one hour...and remained decreased...throughout the four hours."*

"Mean blood pressure was 3-10 mm Hg less than control (88 mm Hg) throughout the four hour period after ONTG therapy, and diastolic blood pressure was 2-8 mm Hg below control (66 mm Hg) during this interval [Afterload reduction]."*

"Consonant with the hemodynamic effects of the preparation...has been its antianginal efficacy demonstrated in a controlled clinical trial."*

*Amsterdam EA, Awan NA, DeMaria AN, et al: Sustained salutary effects of oral controlled-release nitroglycerin on ventricular function in congestive heart failure. *Clinical Cardiology* 2:19-25 (Feb) 1979.

NITRO-BID® Plateau CAPS®
(nitroglycerin) 9 mg, 6.5 mg and 2.5 mg



INDICATIONS: Based on a review of oral nitrate drugs by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows: "Possibly" effective when taken by the oral route, Nitro-Bid Capsules are indicated for the management, prophylaxis or treatment of anginal attacks. Final classification of the less-than-effective indications requires further evaluation.

CONTRAINDICATIONS: Patients with marked anemia, increased intraocular pressure, increased intracranial pressure, glaucoma, hypotension, and idiosyncrasy to this drug.

WARNINGS: Nitro-Bid is not intended to abort the acute anginal episode. Nitro-Bid Capsules must be taken orally, not sublingually.

PRECAUTIONS: Headache is a sign of overdosage, and therefore, dosage should be reduced. Occasionally, elderly patients may have no untoward symptoms while recumbent, but may develop postural hypotension with faintness upon suddenly arising.

ADVERSE REACTIONS: With use of nitrates, transient headache, postural hypotension, flushing, tachycardia and dizziness may occur.

Consult full product disclosure before prescribing.

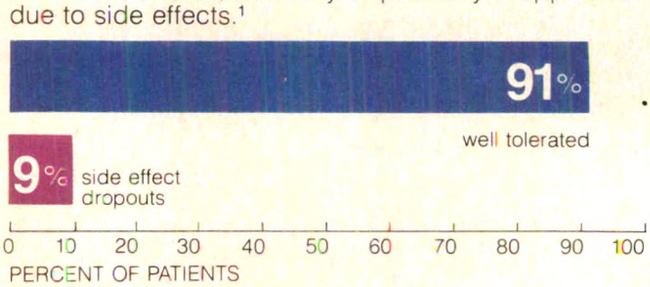
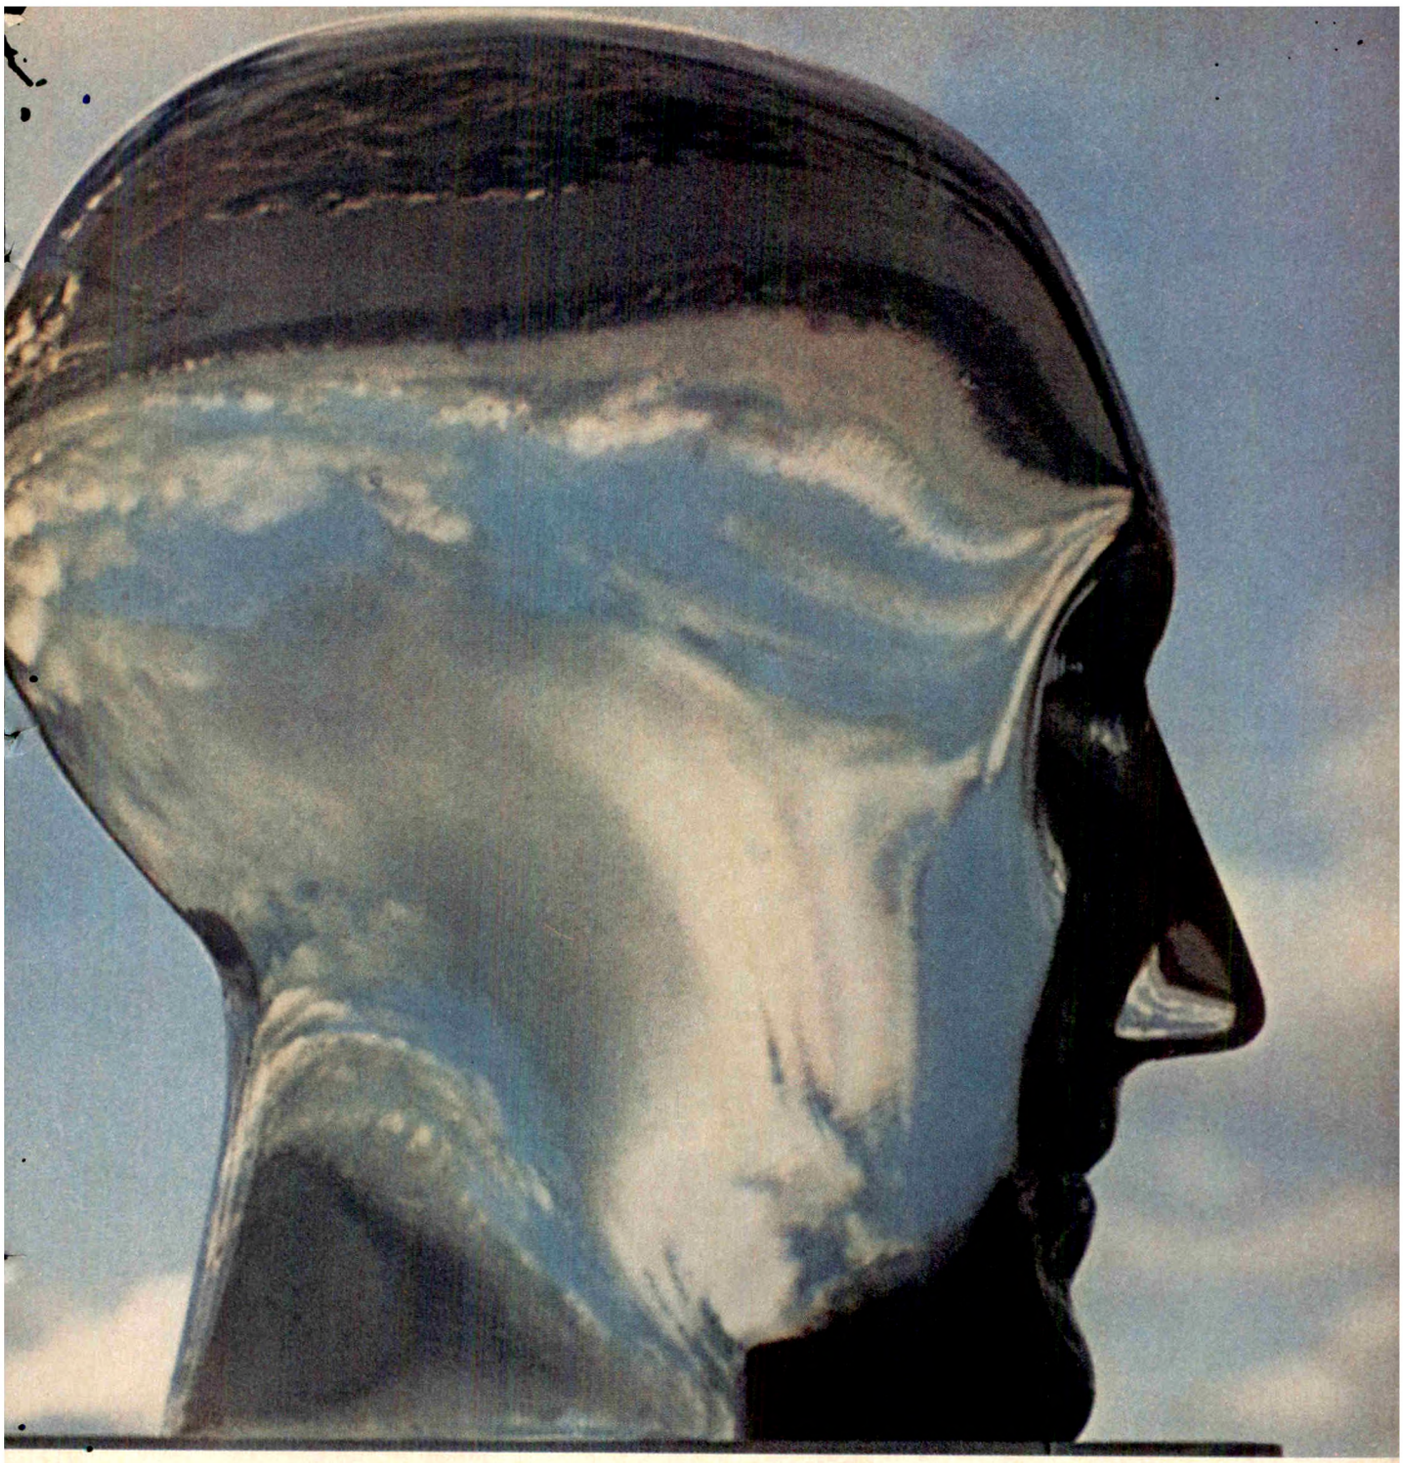
MARION LABORATORIES, INC.
KANSAS CITY, MO. 64137

Combipres.® Today and Tomorrow

well tolerated—only 9% of 484 patients, in 16 clinical trials, definitely or probably dropped out due to side effects.[1]





Effective control in (mild to moderate) hypertension usually with just 2 or 3 tablets daily.

Low incidence of depression, and orthostatic hypotension.*

The most common side effects are dry mouth, drowsiness, and sedation, which generally tend to diminish with time. As with other antihypertensives containing diuretic agents, hypokalemia, hyperuricemia, and hyperglycemia may occur. Drowsiness and sedation may be alleviated by giving the larger portion of the divided dose at bedtime.[2,3]

Convenient morning and bedtime dosage scheduling.

Combipres®

Each tablet contains: Catapres* (clonidine HCl) 0.1 or 0.2 mg, and chlorthalidone, 15 mg

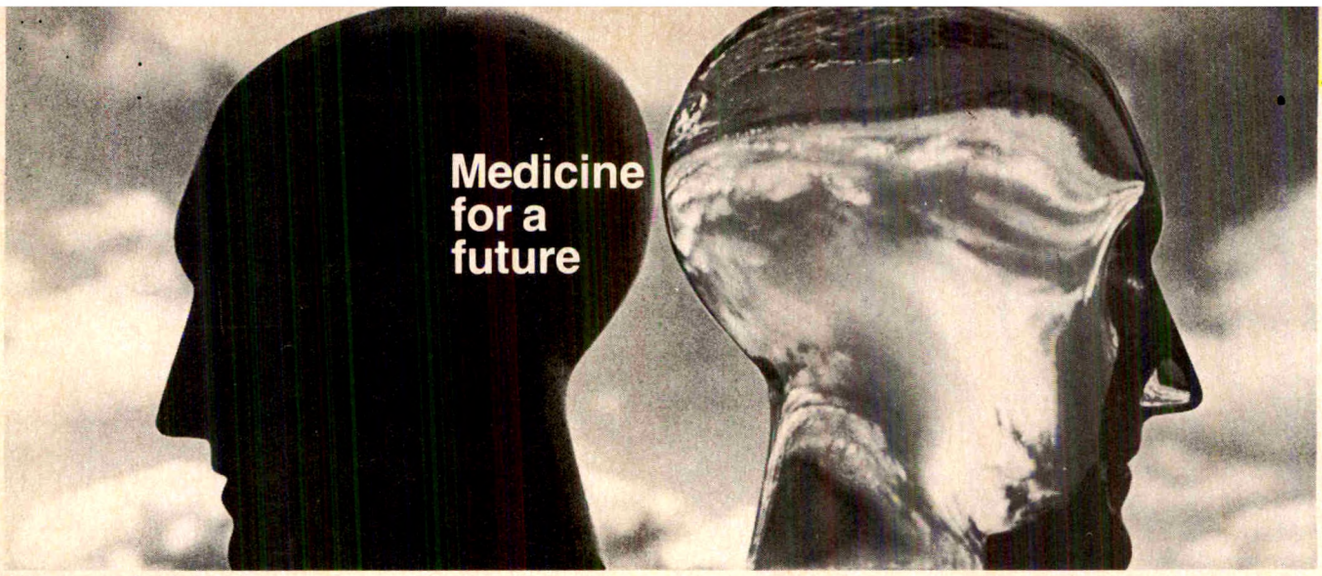
.1 and .2

HYPERTENSION

Combipres is not indicated for initial therapy. It is for patients responsive to its components given separately in equivalent dosages.

Please see brief summary of the prescribing information on the last page of this ad for warnings, precautions, and adverse reactions.

*Orthostatic hypotension has been reported with chlorthalidone and may be potentiated when chlorthalidone is combined with alcohol, barbiturates, or narcotics.



Combipres® .1 and .2

Each tablet contains: Catapres® (clonidine HCl) 0.1 or 0.2 mg, and chlorthalidone, 15 mg

Warning: This fixed combination drug is not indicated for initial therapy of hypertension. Hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension is not static, but must be reevaluated as conditions in each patient warrant.

Indication: The drug is indicated in the treatment of hypertension (see box warning).

Contraindications: Patients with known hypersensitivity to chlorthalidone and patients with severe renal or hepatic diseases.

Warnings: Tolerance may develop in some instances necessitating a reevaluation of therapy.

Usage in Pregnancy: In view of embryotoxicity findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefit outweighs the potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of Combipres in children.

Precautions: When discontinuing Combipres, reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of Combipres therapy or by intravenous phentolamine.

Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect of the clonidine hydrochloride component.This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other antihypertensive agent, Combipres should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Combipres should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmological findings have been recorded with Catapres, in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Patients predisposed toward or affected by diabetes should be tested periodically while receiving Combipres, because of the hyperglycemic effect of chlorthalidone.

Because of the possibility of progression of renal failure, periodic determination of the BUN is indicated. If, in the physician's opinion, a rising BUN is significant, the drug should be stopped.

The chlorthalidone component of Combipres may lead to sodium and/or potassium depletion. Muscular weakness, muscle cramps, anorexia, nausea, vomiting, constipation, lethargy or mental confusion may occur. Severe dietary salt restriction is not recommended in patients receiving Combipres.

Periodic determinations of the serum potassium level will aid the physician in the detection of hypokalemia. Extra care should be given to detection of hypokalemia in patients receiving adrenal corticosteroids, ACTH or digitalis. Hypochloremic alkalosis often precedes other evidence of severe potassium deficiency. Frequently, therefore, more sensitive indicators than the potassium serum level are the serum bicarbonate and chloride concentrations. Also indicative of potassium depletion can be electrocardiographic alterations such as changes in conduction time, reduction in amplitude of the T wave; ST segment depression; prominent U wave. These abnormalities may appear with potassium depletion before the serum level of potassium decreases. To lessen the possibility of potassium deficiency, the diet, in addition to meat and vegetables, should include potassium-rich foods such as citrus fruits and bananas. If significant potassium depletion should occur during therapy, oral potassium supplements in the form of potassium chloride (3 to 4.5 gm/day), fruit juice and bananas should be given.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy.

Clonidine hydrochloride: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one case of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash; impotence, urinary retention; increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Chlorthalidone: Symptoms such as nausea, gastric irritation, anorexia, constipation and cramping, weakness, dizziness, transient myopia and restlessness are occasionally observed. Headache and impotence or dysuria may occur rarely. Orthostatic hypotension has been reported and may be potentiated when chlorthalidone is combined with alcohol, barbiturates or narcotics. Skin rashes, urticaria and purpura have been reported in a few instances.

A decreased glucose tolerance evidenced by hyperglycemia and glycosuria may develop inconsistently. This condition, usually reversible on discontinuation of therapy, responds to control with antidiabetic treatment. Diabetics and those predisposed should be checked regularly.

As with other diuretic agents hypokalemia may occur (see Precautions). Hyperuricemia may be observed on occasion and acute attacks of gout have been precipitated. In cases where prolonged and significant elevation of blood uric acid concentration is considered potentially deleterious, concomitant use of a uricosuric agent is effective in reversing hyperuricemia without loss of diuretic and/or antihypertensive activity.

Idiosyncratic drug reactions such as aplastic anemia, thrombocytopenia, leukopenia, agranulocytosis, and necrotizing angiitis have occurred, but are rare.

The remote possibility of pancreatitis should be considered when epigastric pain or unexplained gastrointestinal symptoms develop after prolonged administration.

Other adverse reactions which have been reported with this general class of compounds include: jaundice, xanthopsia, paresthesia and photosensitization.

Overdosage: *Catapres (clonidine hydrochloride):* Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals abolishes all effects of Catapres overdosage.

Chlorthalidone: Symptoms of overdosage include nausea, weakness, dizziness, and disturbances of electrolyte balance. There is no specific antidote, but gastric lavage is recommended, followed by supportive treatment. Where necessary, this may include intravenous dextrose and saline with potassium administered with caution.

How Supplied: Combipres® 0.1 (Each tablet contains clonidine hydrochloride 0.1 mg + chlorthalidone 15 mg). It is available as pink, oval, single-scored compressed tablets in bottles of 100.

Combipres® 0.2 (Each tablet contains clonidine hydrochloride 0.2 mg + chlorthalidone 15 mg). It is available as blue, oval, single-scored compressed tablets in bottles of 100.

For The Cardiologist Who Wants The Ultimate In Ultrasound Controls.

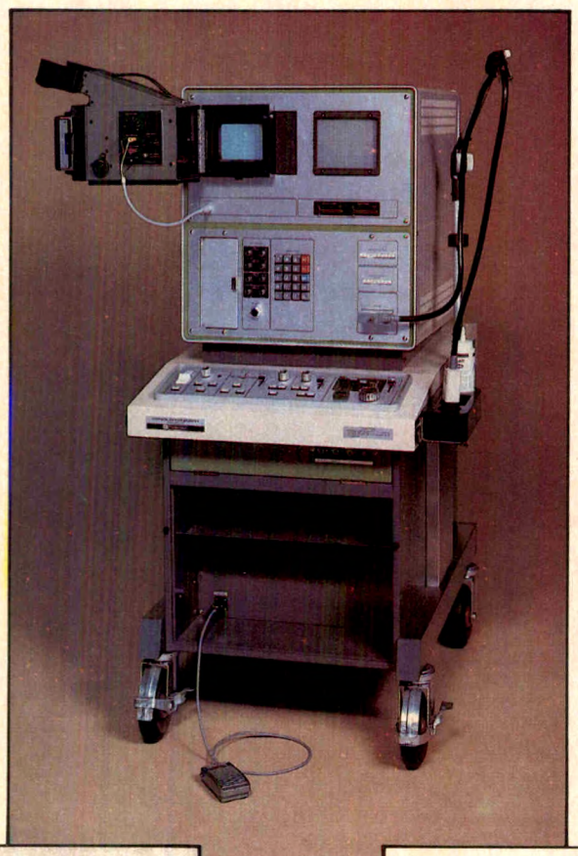
Toshiba's high speed SSH-10A ultrasound electronic sector scanner produces an ultra fine diagnostic image.

Over 16 different parameters can be modified by the cardiologist to maximize image quality in relation to specific patient characteristics.

Valve movement, chamber size and details of the internal structure of the heart can all be clearly observed, measured and diagnosed. Wide range sector angle is a full 78°.

A clear real time, cross sectional B mode image of the heart structure is obtained by simply positioning the probe on the chest wall.

Displayed on the C.R.T. with the B mode image are nonfade ECG and patient I.D. Two angles of the M mode image can also be displayed simultaneously on a second C.R.T. and/or a strip recorder.



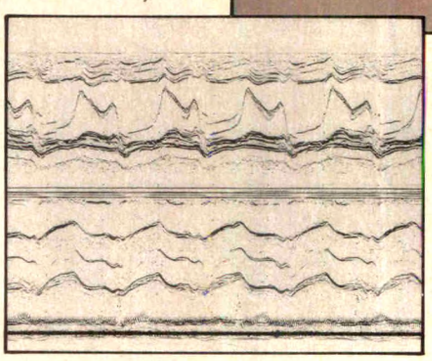
Two UCG traces, M mode tracing and Kymograph studies are additional capabilities.

In short, the SSH-10A gives you the maximum ultrasound information from one mobile unit. So get full information on it now. Contact your local Toshiba representative.

Toshiba Medical Systems,
1154 Dominguez,
Carson, CA 90745

SSH-10A Features:

- Complete Mobility
- Superior Resolution of Electronic Sector Scanning
- Dual M Mode
- 4 Channels of Physiological Monitoring
- Real Time B Mode Cross Sectional Image with ECG and Patient I.D.
- Flexibility for All General Pediatric and Adult Applications



Left: Dual channel M mode showing simultaneously aorta and mitral function.

Right: Long axis left heart.

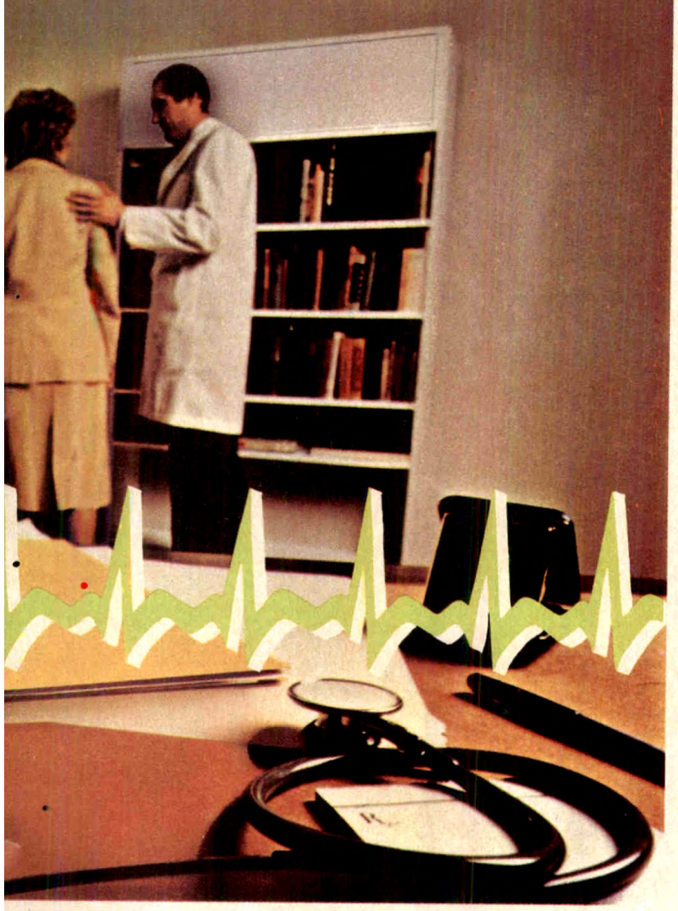
Particularly well suited to initial therapy

Demonstrated efficacy

Intensive clinical studies conducted prior to the release of Norpace (disopyramide phosphate) established its efficacy as an antiarrhythmic agent. And in the short time since its introduction, the drug has been employed in thousands of patients—most frequently initiated in the hospital, where the most challenging, critically ill patients are found. Norpace is now regularly prescribed by increasing numbers of cardiologists who have given it a rapidly expanding base in both hospital and outpatient use.

The efficacy of Norpace, proven in the clinical trials and confirmed in the more difficult hospitalized patients, qualifies it for initial therapy in newly diagnosed cases of ventricular arrhythmia. Such effectiveness was documented during a double-blind, multicenter clinical study involving five investigators.*

...as initial therapy in most outpatients



More favorable side-effects profile

When compared with quinidine sulfate, Norpace is notable for its lower incidence of severe side effects. These are mainly anticholinergic in nature, are usually mild and generally transient. If urinary hesitancy or other genitourinary side effects occur, they are often dose related and frequently may be managed by downward titration of the dose of Norpace. Urinary retention, however, may occasionally occur, particularly in the older patient. Males with benign prostatic hypertrophy are at particular risk.

The lupus-like syndrome often associated with procainamide therapy has not been seen with Norpace, even after several years of continuous Norpace therapy.

Lower dropout rate than quinidine

Efficacy of Norpace, coupled with its low incidence of severe side effects, can mean significantly fewer dropouts among your dysrhythmic patients. In a clinical study involving 62 patients in each treatment group, only 8.1% of patients discontinued Norpace therapy, as compared with 35.5% who discontinued quinidine.

High level of compliance

Even the best medication may not be taken as prescribed if it causes problems for the patient. With Norpace you are prescribing not only an effective medication, but you are prescribing one you can be reasonably confident the patient will take in accordance with your instructions.

Important considerations when prescribing Norpace (disopyramide phosphate)

Patients with compromised cardiac function due to any cause may experience either hypotension or a worsening of cardiac decompensation when taking drugs with negative inotropic effects, and the physician should be aware of this possibility with Norpace. Since Norpace is primarily excreted by the kidney, patients with renal impairment will require a reduced dosage due to prolongation of the effective half-life.

The dosage of Norpace should be individualized for each patient, and the Complete Prescribing Information consulted before prescribing. Special attention to the sections on *Clinical Pharmacology, Warnings,* and *Precautions* will be helpful in determining the proper dosage, particularly for the more complex patient.

Conclusion: Norpace represents a logical choice for both initial and maintenance therapy either in hospitalized patients or in outpatients.

SEARLE

*Data on file, Searle Pharmaceuticals Inc.

Please see the next page for a brief summary of prescribing information.

For specific
ventricular arrhythmias

Norpace®
(disopyramide phosphate)

Right from the start

Before prescribing Norpace (disopyramide phosphate), please consult current complete prescribing information, a summary of which follows:

Indications: Norpace is indicated for suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion).

Norpace is equally effective in treating the above arrhythmias in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Oral Norpace has not been adequately studied in patients with acute myocardial infarction or in patients with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established.

Contraindications: Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug.

Warnings: Severe hypotension has been observed primarily in patients with primary cardiomyopathy or inadequately compensated congestive heart failure. If hypotension develops Norpace should be discontinued promptly unless hypotension is due to the arrhythmia.

Norpace should not be used in the presence of poorly compensated or uncompensated congestive heart failure unless it is exacerbated by or caused by an arrhythmia and proper treatment including optimal digitalization has been accomplished. In patients with marginally compensated heart failure or with a history of heart failure, Norpace may worsen cardiac decompensation. In these patients, progressing congestive heart failure should generally be treated with cardiac glycosides and diuretics and the course of treatment closely followed. Norpace dosage should be reduced or discontinued if adequate control of congestive failure is not attained. Patients receiving concomitant therapy with more than one antiarrhythmic drug must be carefully monitored for serious negative inotropic effects or excessively prolonged conduction, evidenced by widening of the QRS complex and/or prolongation of the Q-T interval.

If first-degree heart block develops, the dosage of Norpace should be reduced. If the block persists, continuation of Norpace must depend upon an assessment of the benefit versus the risk. Development of second- or third-degree AV block or uni-, bi- or trifascicular block requires discontinuation of Norpace, unless the ventricular rate is adequately controlled by a pacemaker.

Because of its anticholinergic properties, Norpace should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken.

Precautions: If significant widening (greater than 25%) of the QRS complex occurs, Norpace should be discontinued. If Q-T prolongation greater than 25% occurs and if ectopy continues, monitor closely and consider discontinuing Norpace.

Patients with atrial flutter or fibrillation should be digitalized prior to Norpace administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits.

The effect of Norpace is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block.

Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of Norpace.

Norpace should be administered cautiously to patients who are receiving or who have recently received other antiarrhythmic drugs. Excessive widening of the QRS complex and/or prolongation of the Q-T interval may occur in such instances.

Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage.

Antiarrhythmic drugs may be ineffective in patients with hypokalemia. Therefore, any potassium deficit should be corrected before instituting Norpace therapy.

Use in Pregnancy and Lactation: Safe use in pregnancy has not been established. Norpace has been reported to stimulate contractions of the pregnant uterus. The use of Norpace in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus.

It is not known whether disopyramide is excreted in human milk. However, studies in rats have shown that the concentration of disopyramide and its metabolites is up to three times greater in milk than in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted.

Labor and Delivery: The effects of Norpace on the fetus during delivery or on the course of labor and delivery are unknown.

Pediatrics: The safety and effectiveness of Norpace in children have not been established.

Adverse Reactions: *Anticholinergic:* dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention. *Genitourinary:* urinary frequency and urgency. *Gastrointestinal:* nausea, pain/bloating/gas, anorexia, diarrhea, vomiting. *General:* nervousness, dizziness, general fatigue/muscle weakness, headache, malaise. *Cardiovascular:* hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain. *Dermatologic:* generalized rash/dermatoses. The following have occurred, but a causal relationship is uncertain: impotence, depression, insomnia, dysuria, and hypoglycemia (usually in patients with impaired liver function). Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported.

Dosage and Administration: Dosage must be individualized for each patient on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg per day given in divided doses four times daily. The recommended dosage schedule for most adults is 150 mg every six hours. For patients weighing less than 110 pounds (50 kg) the recommended dosage is 100 mg every six hours.

If rapid control of arrhythmia is essential, an initial loading dose of 300 mg of Norpace (200 mg for patients weighing less than 110 pounds) is recommended. For patients with cardiomyopathy or possible cardiac decompensation, a loading dose should not be given and the initial dose limited to 100 mg every six hours, with subsequent dosage adjustments made gradually under close monitoring.

See current complete prescribing information for dosage recommendations.

How Supplied: Capsules containing 100 mg or 150 mg of disopyramide base. Available in bottles of 100 and 500 capsules.

The IL Team: for Fluid Therapy Prescription

The IL701, IL702 and IL186 team gives you a more complete picture of cardiopulmonary condition and lets you prescribe fluid therapy with greater confidence.

IL701 Cardiac Output System

For cardiac output by thermal dilution.
Offers these advantages:

- most accurate instrument available
- probe senses injectate temperature at catheter
- completely automated
- 0°C to room temperature injectate
- IL Catheters available: 7F-5F-2F

The **IL702 Recorder** interfaces with the IL701 or IL186 for record-keeping and quality control.

IL186 WEIL ONCOMETER™ System

For measurement of colloid osmotic pressure (COP)
Accurate, fast, easy to operate.
The IL186 helps you:

- quantitate risk of pulmonary edema
- assess fluid balance
- determine extent of cardiopulmonary failure
- predict survival potential
- prescribe appropriate fluid therapy (crystalloid vs. colloid)

For a demonstration of the IL Team, call IL **toll-free: 800 225-4040.**
Or send for literature: 113 Hartwell Avenue, Lexington, MA 02173

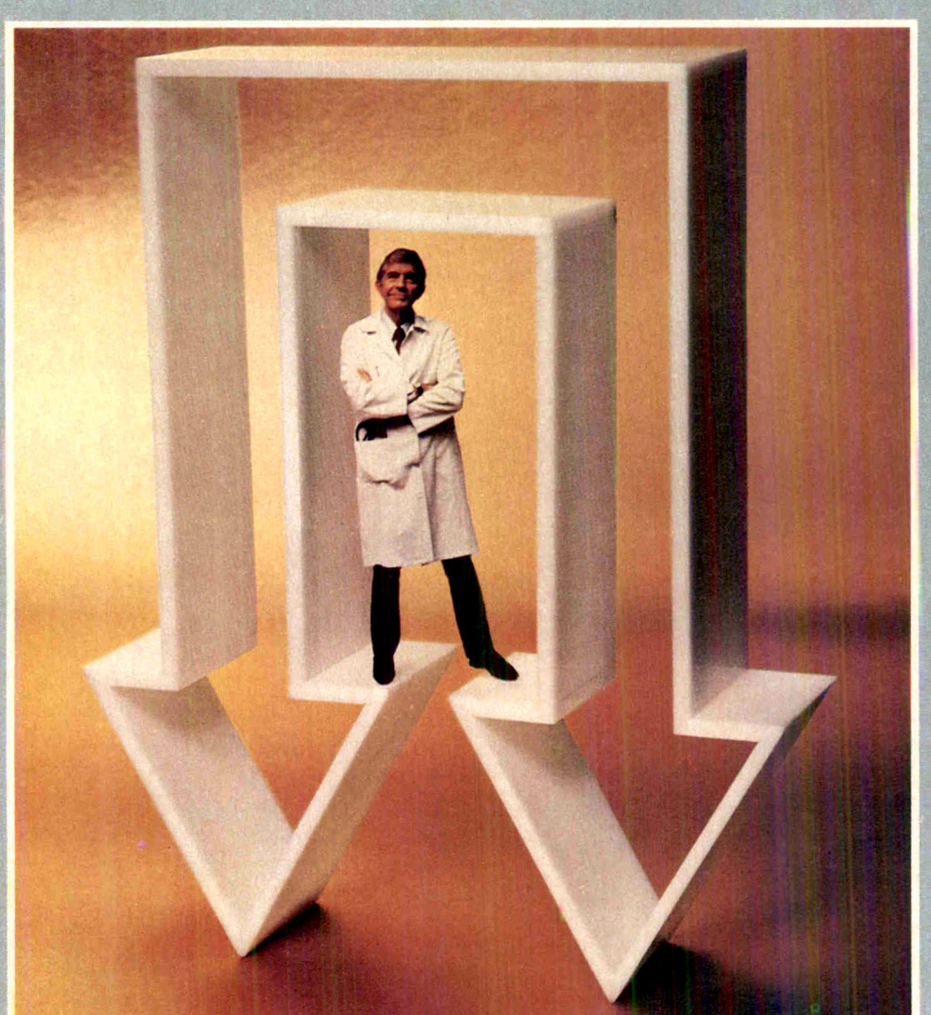
Instrumentation Laboratory
Biomedical Division

A "First-Step" Agent for Your Hypertensive Patient

SELACRYN®

brand of **ticrynafen** 250 mg. Tablet

Usual Dosage: Once a Day



Lowers Blood Pressure

Lowers Uric Acid

Important Benefits for Your Hypertensive Patient

'Selacryn' provides: Three desirable clinical effects in a single agent—antihypertensive, diuretic, uricosuric; Proven once daily round-the-clock antihypertensive control, helping you provide a simplified regimen; Appropriate in primary hypertension regardless of severity, 'Selacryn' is compatible with nondiuretic antihypertensives; Similar to hydrochlorothiazide in effect on electrolytes, no special replacement measures are ordinarily required; and Effective reduction of uric acid levels.

Prescribe 'Selacryn' with Confidence
In most respects, the type, incidence and severity of adverse reactions seen with 'Selacryn' are similar to those seen with thiazides over the years. Standard laboratory tests you use to monitor the course of thiazide therapy are indicated when you prescribe 'Selacryn'.

Discontinue Previous Diuretics
In hypertensive patients, discontinue any previous diuretics for three days before instituting 'Selacryn'. Where feasible, in patients with congestive cardiac failure, discontinue the other diuretic for one to two days before beginning 'Selacryn'. Occasionally, in patients switched from other diuretics without a washout period, nausea, vomiting, flank pain, azotemia, oliguria and, rarely, anuria have been reported.

Maintain Adequate Fluid Intake and Urine Flow with Initial Doses
For patients switched to 'Selacryn' from other diuretics (see above), and for dehydrated patients, hydration is recommended for three days before and three days after starting 'Selacryn'. Since initial doses of 'Selacryn' produce diuresis as well as uricosuria, urinary uric acid concentration does not increase in well-hydrated patients who can increase urine flow.

Reduce Dosage of Concomitant Anticoagulants
'Selacryn' potentiates oral anticoagulants; use caution when using these drugs together. In such patients, reduce the oral anticoagulant to one-quarter or one-half the maintenance dose, monitor prothrombin time through titration until stabilized.

Potassium Supplements Are Usually Not Necessary
but may be advisable in some patients. Since some patients who received 'Selacryn' and Dyrenium® (brand of triamterene) have shown marked elevation of BUN and creatinine, such a combination is not recommended.

See next page for indications and brief summary of prescribing information.

SELACRYN®
brand of ticrynafen 250 mg. Tablet

Logical Successor to Thiazide in First-Step Management

SK&F
a SmithKline company

© Smith Kline &French Laboratories, 19

SELACRYN®

brand of **ticrynafen** 250 mg. Tablet

Before prescribing, see complete prescribing information in SK&F literature. The following is a brief summary.

Indications: Hypertension, with or without elevated uric acid levels. Salt and water retention states associated with congestive cardiac failure.

Contraindications: Anuria, severe or progressive renal disease, hypersensitivity to the drug, known renal uric acid calculi.

Warnings: Potentiates the action of oral anticoagulants; caution should be exercised when these agents are used with 'Selacryn'; reduce anticoagulant dosage to ¼ or ½ of the maintenance dose, and carefully monitor prothrombin time until stabilized.

Concomitant use with triamterene is not recommended since a marked elevation of BUN and creatinine may occur.

Not appropriate in hepatic ascites. May precipitate azotemia in progressive or advanced renal disease; therefore, frequent electrolyte, creatinine and BUN determinations should be performed early in therapy and periodically thereafter. Discontinue the drug if renal impairment progresses.

Pregnancy, Nursing: 'Selacryn' crosses the placental barrier in animals. Routine use of diuretics during normal pregnancy is inappropriate and exposes mother and fetus to unnecessary hazard. Use in pregnancy requires weighing anticipated benefits against possible hazards. Generally, nursing should not be undertaken while a patient is on a drug.

Precautions: Substantial uricosuria occurs within hours after the first dose of 'Selacryn'; for this reason, hypertensive patients switching from other diuretics should discontinue diuretics for 3 days before starting 'Selacryn'; where feasible, diuretics should be discontinued for 1 to 2 days in patients with congestive cardiac failure. Fluid intake should be increased to approximately 1500 cc. per day for up to 3 days before and 3 days after initiation of 'Selacryn' therapy in patients switched to 'Selacryn' from other diuretics and in patients who may be dehydrated, particularly if the patients are hyperuricemic.

Acute attacks of gout may be precipitated; continue 'Selacryn' (brand of ticrynafen). colchicine may be added to control the acute attack. Observe patients for signs of electrolyte imbalance, i.e., hypokalemia, hyponatremia, hypochloremic alkalosis. Periodic determinations of electrolytes to detect possible imbalance should be performed. Concomitant use with cytotoxic agents requires caution and individualization of dosage and management. Effects on glucose metabolism are similar to those seen with thiazides. Insulin requirements may be affected; hyperglycemia and glycosuria may occur in patients with latent diabetes. Elevation of BUN and/or serum creatinine can occur during diuretic therapy.

Children: Safety and effectiveness in children have not been established.

Drug Interactions: Exercise caution when administering with other highly protein-bound drugs, especially anticoagulants; reduce anticoagulant dose to ¼ or ½ of the maintenance dose and carefully monitor prothrombin time until stabilized. (See Warnings.) Concomitant use with triamterene is not recommended since a marked elevation of BUN and creatinine may occur.

The drug causes a decrease in excretion of salicylates and organic acids, e.g., penicillin. Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Adverse reactions seen with 'Selacryn' (brand of ticrynafen) in controlled studies were approximately the same as those seen with hydrochlorothiazide. Except where noted, the following adverse effects seen with 'Selacryn' have been reported in a small number of patients, e.g., approximately 1 in 100: anorexia, nausea, vomiting, dyspepsia, cramping, diarrhea, constipation, headache (approximately 4 in 100), dizziness/lightheadedness (approximately 9 in 100), paresthesia, somnolence, insomnia, syncope, vertigo, orthostatic hypotension, palpitation, rash, urticaria, pruritus, rare cases of fever and interstitial nephritis. Tiredness/fatigue (approximately 4 in 100), hyperglycemia, glycosuria, muscle cramps, weakness, bitter taste and dryness in mouth, exacerbation of gout, renal colic or costovertebral pain. Abnormal liver function tests and jaundice have been reported in a few patients.

Occasionally, patients who received 'Selacryn' without a washout period (See Precautions) experienced nausea, vomiting, flank pain, azotemia, oliguria and, rarely, anuria; these effects were reversible.

The following adverse reactions have not been reported to date with 'Selacryn' but have occurred with thiazides or other diuretics: pancreatitis, sialadenitis, xanthopsia, purpura, photosensitivity, necrotizing angiitis, Stevens-Johnson syndrome, respiratory distress, anaphylactic reaction, leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia, restlessness and transient blurred vision.

Supplied: Light blue, round, scored, monogrammed tablets of 250 mg. in bottles of 100, and in Single Unit Packages of 100 (intended for institutional use only).

Congestive Heart Failure

Mechanisms, Evaluation and Treatment

Dean T. Mason, M.D.

This rare treatment of such a multifaceted subject provides an unusual opportunity for the busy clinician to add to his knowledge in a minimum amount of time. Any area of immediate interest can be rapidly located and as much data as needed can be quickly extracted. The concentration on improved clinical management will be appreciated by every internist, cardiologist, generalist, and any professional involved in cardiovascular medicine.

Dean Mason, President of the American College of Cardiology, has organized this monograph within the three areas relevant to an understanding of congestive heart failure: *mechanisms, evaluation* and *treatment*. Fifty-six recognized authorities have been assembled by Dr. Mason, each contributing their expertise to make this book the foremost text covering the highly important and common disorders of abnormal heart function.

This presentation of recent advances in basic research and clinical progress has been highly acclaimed for its major contribution to the improvement of patient care. We invite you to see if you don't agree. Order and take 30 days to look over the book. If you're not totally satisfied, return it.

About the author . . . Dean T. Mason, M.D.

Professor of Medicine, Professor Physiology, Chief of Cardiovascular Medicine, University of California, School of Medicine, Davis.

President, American College of Cardiology; President, Western Society for Clinical Research.

Member of the American Board of Internal Medicine Cardiovascular Diseases.

Has authored more than 400 original articles on cardiovascular science and clinical cardiology.

Serves on the editorial boards of The American Journal of Cardiology, The Journal of Clinical Investigation, Circulation, Chest, Clinical Pharmacology and Therapeutics, Catheterization and Cardiovascular Diagnosis, and Heart and Lung.

Recipient of Experimental Therapeutics Award in 1973 from the American Society of Pharmacology and Experimental Therapeutics, the Research Awards in 1965 from the American Therapeutic Society, and the Theodore and Susan B. Cummings Humanitarian Awards in 1972, 1973, and 1975 from the U.S. State Department and the American College of Cardiology.

THE START OF A WHOLE NEW TREND IN AMBULATORY MONITORING.

THE TRENDSETTER.™

A DYNAMIC, NEW CARDIOVASCULAR SYSTEM FOR IMPROVED PATIENT MANAGEMENT FROM DEL MAR AVIONICS.

The challenge: greater accuracy, control and flexibility in processing Holter Monitoring™ data. **The solution:** the Trendsetter, a dynamic new system that allows abnormalities to be detected and documented with unprecedented speed and specificity. **The result:** more precise and thorough evaluation of cardiac status — for improved patient management.

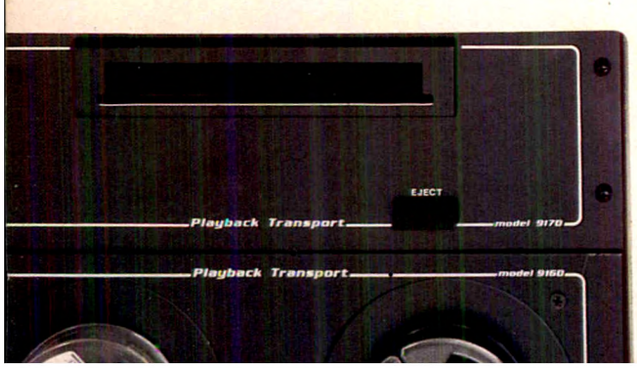
DETECT ARRHYTHMIAS WITH UNPARALLELED ACCURACY.

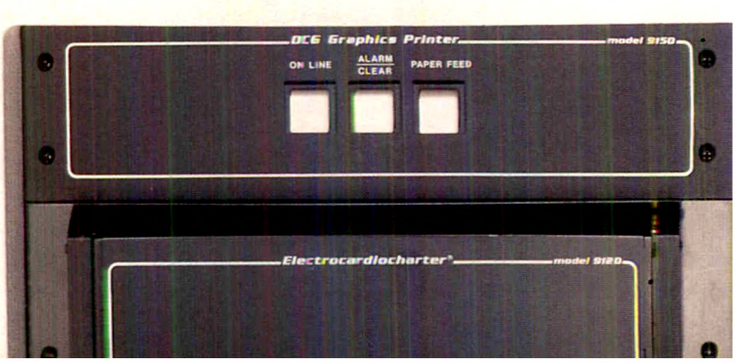
The system's Arrhythmia Analyzer is "operator-taught" to recognize each patient's unique normal and variant waveforms, and to compare all subsequent waveforms to the learned patterns. The Analyzer then categorizes and counts all such waveforms — making arrhythmia detection precise and specific for each patient.

EVALUATE AMBULATORY ECG, BLOOD PRESSURE, AND PACEMAKER DATA WITH A SINGLE INTEGRATED SYSTEM.

The Trendsetter learns, examines, tabulates, and formats reports of data recorded by all Del Mar Avionics Electrocardiocorder® models — including the new Cartridge recorder.

- **Computerscan™** — hourly quantification of heart rate, ECG rhythms, ectopy, patterns of occurrence, and ST segment level. Includes a comprehensive summary report.
- **Pressurescan™** — time-correlated systolic/diastolic values and heart rate in graphical and tabular formats, in addition to a printed summary.





- **Pacerscan™** — hourly quantification of heart rate, total beats, paced beats, and pacemaker failures to capture, sense and output.

REDUCE PROCESSING TIME WITH NEW X240 SCANNING SPEED.

Selectable scan speeds of X240, X120 or X60 provide the operator with a speed-control range to assist in generating comprehensive reports rapidly — all with complete accuracy. Trend records of heart rate and ST segment level also include hourly tabulation of ectopy and density of occurrence — all automatically printed, without operator supervision, in only 6 minutes.

SELECT REPORT FORMATS TAILORED TO YOUR DIAGNOSTIC NEEDS.

Select the information you require to better manage each patient: trend records of heart rate, ST segment level and blood pressure; 2-channel ECG documentation; hourly tabulations of ECG activity, pacemaker activity, and blood pressure; graphic/histographic charts of recorded data, or any combination you predetermine.

PINPOINT ABNORMALITIES FOR EXACT DOCUMENTATION.

Multiscan Display Scope presents ECG in four different modes for examination:

- **Scan Mode** — high-speed superimposed scanning of two channels of continuous ECG with R-R interval bar graph.
- **Slide Mode** — frozen real-time ECG display from both leads of an 11-second window which operator can slide through full 180-second memory.
- **Page Mode** — 3 separate real-time ECG displays of 60 seconds each from either channel.
- **Jog Mode** — full 180-second display of continuous ECG with continuous write-out capability.

CORRELATE ABNORMALITIES WITH SYMPTOMS AT A GLANCE.

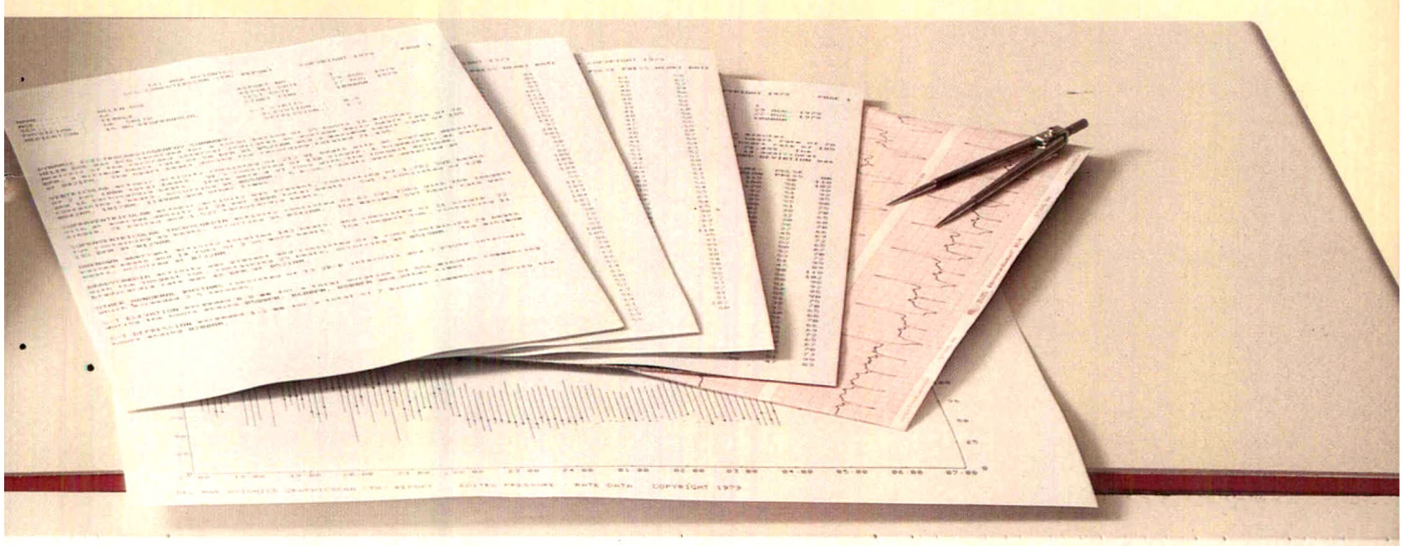
Data Display Scope presents events initiated by the Arrhythmia Analyzer, Pacer Analyzer,™ Patient Event Button, or the operator — all in time-correlated format. High-speed Auto-Search allows the operator to recall precise areas of interest as referenced on the Display Scope.

STORE MULTIPLE PATIENT FINDINGS WITH INTEGRAL COMPUTER DATA STORAGE MODULE.

Recorded data for up to 30 patients can be stored and recalled for subsequent review and formatting.

USE EITHER REEL-TO-REEL OR CARTRIDGE RECORDERS.

The Trendsetter can handle both. It processes tapes from *all* models of Del Mar Avionics recorders, including the new, convenient Cartridge recorder.



THE MODEL DCG VII DYNAMIC ELECTROCARDIOSCANNER®

THE TRENDSETTER™

THE START OF A WHOLE NEW TREND IN AMBULATORY MONITORING.

Myocardial Prostaglandin E Release by Nitroglycerin and Modification By Indomethacin

ESTEBAN MORCILLIO, MD, PhD
PHILIP R. REID, MD, FACC
NORMAL DUBIN, PhD
RAMESH GHODGAONKAR, BPharm
BERTRAM PITT, MD, FACC

Baltimore, Maryland

In open chest dogs, studies were made of the effects of intravenous trinitroglycerin (10 μg/kg per min) on circumflex arterial coronary blood flow, coronary vascular resistance, systemic arterial pressure and myocardial prostaglandin E production before and after indomethacin (n = 9) or indomethacin vehicle (n = 5). During a 30 minute trinitroglycerin infusion, coronary sinus prostaglandin E concentration increased significantly (approximately +41 percent, $p < 0.01$) without significant changes in left atrial prostaglandin E concentration. After indomethacin (5 mg/kg), but not indomethacin vehicle alone, a second trinitroglycerin infusion (10 μg/kg per min) produced a significantly smaller decrease in coronary vascular resistance ($p < 0.05$) and systemic blood pressure ($p < 0.01$) and no increase in coronary sinus prostaglandin E ($p < 0.001$) by comparison with control values. The heart rate response to trinitroglycerin was significantly greater ($p < 0.05$) after than before indomethacin. This study suggests that the mechanism of action of trinitroglycerin may be at least partially mediated through the prostaglandin system.

The mechanism of action of trinitroglycerin remains incompletely understood despite use of this agent in the management of angina pectoris for over a century. Its most prominent pharmacologic response, vasodilation, has not been clearly related with any known transmitter or receptor and therefore is classified as a "direct" effect.[1]

In recent studies[2,3] the coronary vasodilation elicited by some naturally occurring substances such as norepinephrine, adenosine triphosphate, adenosine diphosphate, bradykinin, angiotensin II and arachidonate itself has been shown to be at least partially mediated through biosynthesis and release of prostaglandin-like substances from the heart, generally characterized as prostaglandin E[2,3] but also prostaglandin A[4] and others.[5] It has been postulated that both prostaglandin E and prostaglandin A play a physiologic role in the local regulation of the coronary blood flow,[6–8] but the supportive data have not been found in all studies.[9]

Prostaglandins E and A also appear to be involved in the regulation of systemic arterial blood pressure.[5,8,10] In addition, the actions of hydralazine,[11] diuretic drugs such as furosemide[12] and spironolactone[13] and beta adrenergic blocking agents such as propranolol and pindolol,[14] all have significantly reduced effects when administered after indomethacin, an inhibitor of prostaglandin synthetase.[15] Thus, both endogenously released and exogenously administered agents may have coronary and systemic effects at least partially mediated through the prostaglandin system.

Because the effects of other vasoactive agents have been linked to prostaglandin biosynthesis and some effects of trinitroglycerin differ in vivo and in vitro conditions,[16] we examined the role of prostaglandin E in mediating the effects of trinitroglycerin on coronary vascular resistance and systemic blood pressure.

From the Divisions of Cardiovascular Medicine and Clinical Pharmacology and the Department of Pharmacology, The Johns Hopkins University, Baltimore, Maryland. This study was supported in part by Grants R01-HL18512-02 and 5P50 HL17655 from the National Institutes of Health, Bethesda, Maryland. Manuscript received June 19, 1979; revised manuscript received August 13, 1979, accepted August 31, 1979.

Address for reprints: Philip R. Reid, MD, The Johns Hopkins Hospital, Osler 524, 601 North Broadway, Baltimore, Maryland 21205.

Methods

Surgical preparation: Fourteen mongrel dogs of either sex, weighing 20 to 34 kg, were initially anesthetized with intravenous sodium thiamylal, 20 mg/kg body weight, and anesthesia was maintained with alpha chloralose. After endotracheal intubation the animals were ventilated with room air using a Harvard respirator. Mean and phasic aortic pressures were measured through a cannula positioned in the aortic arch by way of the left common carotid artery and connected to a Statham P23Db transducer. Heart rate was measured from the surface electrocardiogram. A left anterolateral thoracotomy was performed in the fifth intercostal space and the heart suspended in a pericardial cradle.

The left circumflex coronary artery was isolated approximately 5 mm below the bifurcation of the left coronary artery, and a cuffed electromagnetic flow probe (Biotronex series 6000 flow probe) was placed around the vessel and connected to a Biotronex model 613 sine wave electromagnetic flowmeter. Zero blood flow was obtained periodically during the experiment by a 5 second occlusion of the artery distal to the probe.

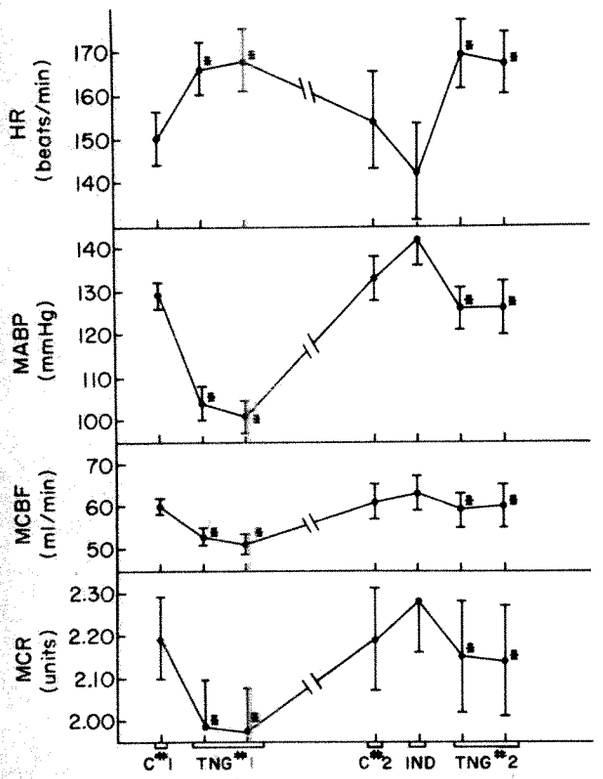

FIGURE 1. Summary of results in nine experiments examining the effects of administration of 10 μg/kg per min of trinitroglycerin (TNG) at 15 and 30 minutes on heart rate (HR), mean arterial blood pressure (MABP), mean left circumflex arterial blood flow (MCBF) and mean circumflex arterial resistance (MCR) before and after indomethacin (IND) (5 mg/kg). C#1 and C#2 refer to observations during the first and second control periods, respectively. Data are expressed as mean values ± standard error of the mean. The asterisks refer to the statistical significance ($p < 0.05$) of the difference (1) between values during the first infusion of nitroglycerin (TNG #1) versus those during the first control period, (2) values after indomethacin versus those during the second control period, and (3) values in the second control period versus those after the second infusion of nitroglycerin (TNG #2).

Systemic pressure, mean circumflex coronary blood flow and the electrocardiogram were recorded on a multichannel polygraph (Gould Brush 200). Mean coronary resistance was calculated according to the formula: Resistance (units) = Mean aortic pressure (mm Hg)/Mean coronary blood flow (ml/min).

Catheters were placed in the left atrium and coronary sinus for blood samples, and the left external jugular vein was cannulated for drug injections.

Experimental design: In nine dogs, after a 15 minute stabilization period, control measurements were made, at 0 time and at 15 minutes, of systemic arterial pressure, coronary blood flow, heart rate and left atrial and coronary sinus prostaglandin concentration. Trinitroglycerin, 10 μg/kg per min, was then infused intravenously for 30 minutes (1.1 ml/min). During the infusion, left atrial and coronary sinus blood samples for measurement of prostaglandin E were obtained at 15 and 30 minutes. The trinitroglycerin infusion was stopped after 30 minutes, a 1 hour recovery period was permitted, and then blood samples were obtained for measurement of left atrial and coronary sinus prostaglandin E. Thereafter indomethacin (5 mg/kg) was infused intravenously over a 10 minute period, and 30 minutes later, the trinitroglycerin infusion (10 μg/kg per min) was repeated for 30 minutes. Hemodynamic measurements and left atrial and coronary sinus blood samples for prostaglandin E were again obtained at 15 and 30 minutes during the second trinitroglycerin infusion. In five control dogs, the same protocol was followed, except that indomethacin vehicle (see later) was used.

Prostaglandin measurement: Left atrial and coronary sinus blood samples were immediately placed into chilled tubes containing 15 μg of indomethacin and centrifuged at 3,000 rpm for 10 minutes. The plasma was carefully separated and placed in glass tubes and stored at −20° C until analysis. After extraction of the acidified plasma with ethylacetate, prostaglandin E concentration was determined by a modified[17] radioimmunoassay method.[18] Although the antibody was prepared using prostaglandin E_2, it demonstrated a high cross-reactivity in prostaglandin E_1 (131 percent), but less than 1 percent against other prostaglandins tested. Therefore, the results are expressed as total prostaglandin E concentration (pg/ml). This method provided a coefficient of variation of less than 10 percent within an assay, and less than 15 percent between repeated assays on the same samples.

Drugs: Trinitroglycerin solution was prepared by dissolving crushed sublingual tablets in saline solution. Indomethacin solution (7.5 mg/ml) was prepared by adding a warm solution (50° C) of 300 mg sodium bicarbonate in 30 ml 0.9 percent sodium chloride solution to 300 mg indomethacin dissolved in 10 ml of 90 percent ethanol.

Statistical analysis: The paired Student's *t* test was applied to the hemodynamic values and a two-way analysis of variance for the prostaglandin E data. Results were expressed as the mean ± standard error of the mean. Statistical significance was accepted if $p > 0.05$.

Results

First trinitroglycerin infusion: Compared with control measurements (Fig. 1) at 15 and 30 minutes, the first intravenous trinitroglycerin infusion (10 μg/kg per min) produced significant decreases in systemic mean arterial pressure (from 129 ± 2.5 to 102 ± 3 mm Hg at 30 min, $p < 0.001$), mean circumflex blood flow (from 60.5 ± 1.5 to 51.5 ± 1.6 ml/min at 30 min, $p < 0.01$) and mean circumflex arterial resistance (from 2.19 ± 0.9 to

1.85 ± 0.11 units at 30 minutes, p <0.01). These responses were associated with a significant rise in both heart rate (from 150.5 ± 6.6 to 166 ± 5.1 beats/min at 30 minutes, p <0.01) and coronary sinus prostaglandin E concentration (from 410 ± 50 to 524 ± 80 pg/ml at 30 minutes, p <0.05) without a significant rise in left atrial prostaglandin E (Fig. 2). This resulted in a significant increase in the coronary sinus left atrial difference (from +60 ± 30 to +160 ± 52 pg/ml at 30 minutes, p <0.01). One hour after discontinuation of the trinitroglycerin infusion, hemodynamic and prostaglandin E values had returned to values close to those of control period 1 (Fig. 1 and 2).

Indomethacin infusion: Thirty minutes after the start of the indomethacin infusion (5 mg/kg), there was a significant increase in systemic mean arterial pressure (142 ± 6 versus 132.5 ± 7 mm Hg, p <0.05) and a decrease in heart rate (155 ± 10 versus 142 ± 10 beats/min, p <0.05) compared with values in control period 2 (Fig. 1). The mean circumflex arterial resistance was also higher (2.18 ± 0.12 versus 2.28 ±0.11 units p <0.05), whereas coronary sinus prostaglandin E concentration decreased (490 ± 75 versus 335 ± 31 pg/ml, p <0.001) to produce a negative coronary sinus-left atrial difference (112 ± 42 versus −85 ± 33 pg/ml, p <0.001) when compared with values in control period 2.

Second trinitroglycerin infusion: During the second trinitroglycerin infusion and compared with indomethacin (Fig. 1) there was a significant decrease in systemic mean arterial pressure (to 125.5 ± 6.5 mm Hg, p <0.01) and mean circumflex coronary arterial resistance (to 2.16 ± 0.13 units, p <0.05). However, after indomethacin, the second trinitroglycerin infusion produced a significantly smaller decrease in both mean systemic arterial pressure (−15 ± 7 versus −27 ± 4 mm Hg, p <0.01) and mean circumflex arterial resistance (−0.7 ± 0.2 versus −1.4 ± 0.1 units, p <0.05) compared with values in the first trinitroglycerin infusion. In addition, the absolute values achieved at 30 minutes during the first infusion were significantly higher than those observed during the second infusion for both systemic pressure (125 ± 6.5 versus 102 ± 3 mm Hg, p <0.001) and circumflex arterial resistance (2.2 ± 0.1 versus 1.9 ± 0.1 units, p <0.01).

The mean heart rate response to the first trinitroglycerin infusion at 30 minutes (166.5 ± 5.1 beats/min) was not significantly different from that observed at the same time during the second infusion (167 ± 7 beats/min). However, the change in heart rate was significantly greater (p <0.01) when the response at 30 minutes from control for the first trinitroglycerin infusion (±16 ± 6 beats/min) was compared with the response during the second infusion (+25 ± 7 beats/min) 30 minutes after indomethacin.

Control infusion: During the five control experiments with the indomethacin vehicle, no significant differences were observed in either the hemodynamic responses (Fig. 3) or left atrial and coronary sinus prostaglandin E levels (Fig. 4) when values during the first and second trinitroglycerin infusions were compared.

Discussion

This study demonstrates that during an intravenous infusion of trinitroglycerin there was a significant increase in myocardial prostaglandin E production associated with the expected fall in systemic blood pressure and decrease in coronary vascular resistance. With at least partial inhibition of myocardial prostaglandin E

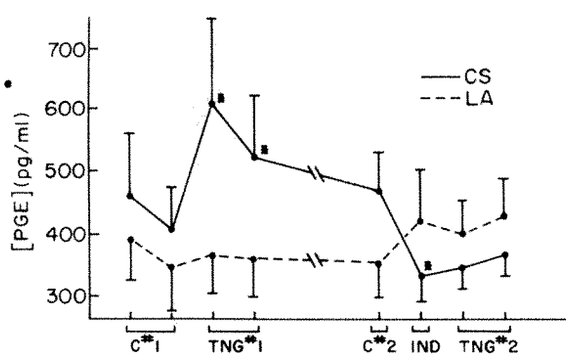

FIGURE 2. Prostaglandin E (PGE) concentrations in the coronary sinus (CS) and left atrium (LA) in the nine experiments shown in Figure 1. The asterisks refer to the statistical significance when the coronary sinus-left atrial differences were compared with values in the first and second control periods. Abbreviations as in Figure 1.

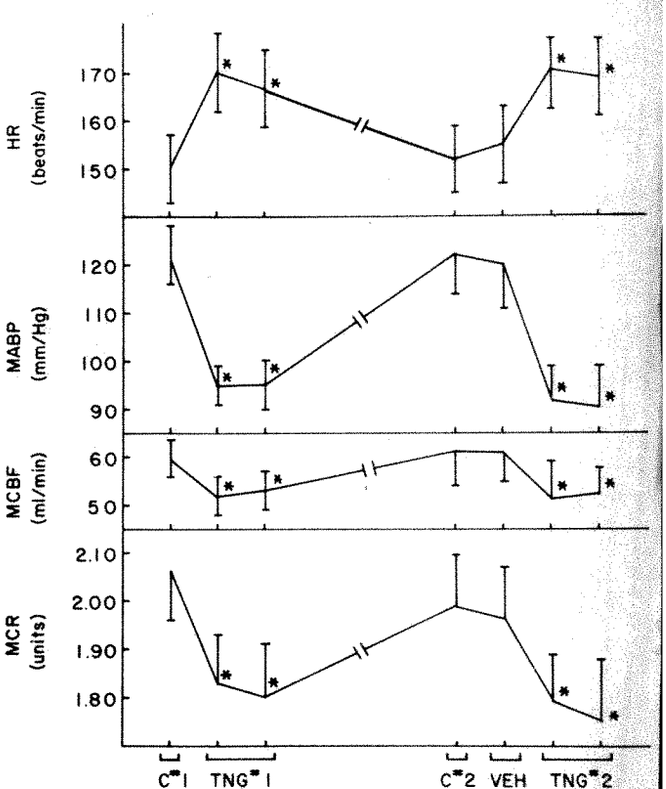

FIGURE 3. Results in the five experiments in which indomethacin vehicle (VEH) was used. Trinitroglycerin (TNG) produced similar responses during both infusions. Format and abbreviations as in Figure 1.

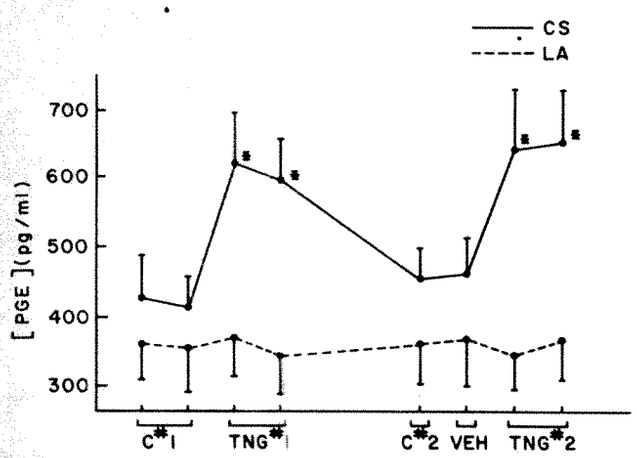

FIGURE 4. Changes in prostaglandin E (PGE) levels in five control experiments in which indomethacin vehicle (VEH) was used. Format and abbreviations as in Figure 2.

production after indomethacin (Fig. 2), there was a significantly lesser reduction ($p < 0.05$) in coronary vascular resistance and systemic blood pressure during the second trinitroglycerin infusion. When the indomethacin vehicle was substituted (Fig. 3), the hemodynamic responses were unaltered and prostaglandin E levels again increased with the second trinitroglycerin infusion (Fig. 4). These data suggest that trinitroglycerin may have its mechanism of action at least partially mediated through the prostaglandin system.

Responses of various prostaglandins to nitroglycerin: vasodilation versus vasoconstriction: The radioimmunoassay[17,18] used in our study does not permit differentiation between prostaglandin E_1 and E_2. Both of these prostaglandins produce changes in coronary vascular resistance, although in most studies[19–21] prostaglandin E_1 is more potent in production of vasodilation and in several animal species prostaglandin E_2 may actually produce coronary vasoconstriction. It is also possible that other prostaglandins were elaborated in response to the trinitroglycerin infusion. Some of these, particularly prostacyclin (PGI_2), appear to be much more potent than prostaglandin E_1 in producing vasodilation,[21] whereas others such as thromboxane are more potent in producing vasoconstriction. Thus, the observed increase in prostaglandin E after trinitroglycerin may have reflected a balance between prostaglandins producing vasodilation and vasoconstriction. Although prostacyclin is a much more potent vasodilator than prostaglandins E_1 and E_2 and may be involved as the major intrinsic prostaglandin that regulates local vascular tone, a pharmacologic agent such as trinitroglycerin could selectively enhance prostaglandin E to produce vasodilation without increasing prostacyclin or other prostaglandins. This possibility is given support by recent observations from our laboratory[22] that demonstrated that isosorbide dinitrate produced an increase in prostaglandin E with no change in prostaglandin F.

Mechanism of interaction between trinitroglycerin and the prostaglandin system: The mechanism cannot be clearly defined from this study alone. The increase in coronary sinus prostaglandin E may represent de novo biosynthesis because others[23] have found that prostaglandins are not stored. It is possible that trinitroglycerin partially inhibited prostaglandin E (or other prostaglandin) metabolic inactivation. However, our data suggest that if inhibition of metabolism occurred it was at sites other than the lung because the left atrial prostaglandin E concentration did not increase significantly after infusion of trinitroglycerin (Fig. 2).

Prostaglandin inhibition by indomethacin: After indomethacin, there was a significant increase in systemic pressure with a presumed reflex reduction in control heart rate (Fig. 2). Similar results after indomethacin were observed in other studies[22] and these changes may represent suppression of basal levels of prostaglandins as observed in the left atrial prostaglandin E concentrations in our study. The heart rate response to the second trinitroglycerin infusion was not reduced despite a lesser decrease in systemic blood pressure. In fact, the change in heart rate was significantly greater when comparing the increase observed in control period 1 during the first trinitroglycerin infusion with the increase noted in control period 2 during the second trinitroglycerin infusion. Other studies[24] have demonstrated that prostaglandin may play a modulating role in release of neurotransmitter stores and perhaps prostaglandin inhibition permitted an exaggerated heart rate response to any reduction in systemic blood pressure.

Implications of study: Although our animal model was nonischemic by experimental design, consideration should be given to the possibility that the reduction in blood pressure produced by trinitroglycerin induced ischemia and subsequent prostaglandin release. Although our data do not exclude this possibility, the hypothesis is unlikely because the changes in blood pressure were not extreme, the standard electrocardiogram (lead II) showed no evidence of ischemia and the appearance of the heart did not change during the trinitroglycerin infusion. Furthermore, data from other studies[25] in which trinitroglycerin was used during coronary occlusion suggest that ischemia is reduced. Use of the anesthetized open chest dog in our study may have artificially altered responses to pharmacologic agents. Future studies should reexamine this response in unanesthetized intact animals and evaluate the role of other prostaglandins (especially prostacyclin) as these assays become available. In addition, the animal data require confirmation in human subjects because prostaglandin responses may vary greatly between species. We believe that our study provides preliminary evidence that trinitroglycerin and possibly other organic nitrates[23] may have their mechanism of action mediated, in part, through the prostaglandin system.

Evidence for a Flow-Independent Contribution to the Phenomenon of Thallium Redistribution

JOSEPH L. GERRY, Jr., MD

JOHN T. FLAHERTY, MD, FACC
MYRON L. WEISFELDT, MD, FACC

Baltimore, Maryland

Although thallium-201 is known to redistribute slowly into regions of ischemic myocardium after restoration of blood flow, it is not clear to what extent normalization of flow is an essential requirement for the redistribution process. In a search for a flow-independent component of thallium redistribution, 12 dogs with stenosis of the circumflex coronary artery underwent atrial pacing for either 20 minutes (group I, 6 dogs) or 2 hours (group II, 6 dogs). Radioactive thallium and radioactive microspheres, 7 to 10 μ, were injected after 10 minutes of atrial pacing in both groups. Pacing resulted in a 40 percent reduction in subendocardial blood flow to the circumflex-perfused myocardium in both groups I and II. This relative reduction in flow was maintained at a stable level over the 2 hour pacing period in group II. Thallium activity in the relatively ischemic zone was significantly greater in dogs with 2 hours of pacing (group II) than in those with 10 minutes of pacing (group I). Redistribution of thallium occurred despite the continued presence of reduced flow in circumflex-perfused endocardial tissue. These data suggest that a significant component of thallium redistribution may be flow-independent.

The radioisotope thallium-201 is a useful agent for determining the distribution of myocardial blood flow noninvasively with use of the gamma camera.[1] Stress testing with thallium injected at the peak of exercise allows detection of underperfused myocardial segments fed by stenotic coronary arteries.[2] It has been observed[3] that myocardial segments exhibiting relatively reduced thallium activity immediately after stress testing often are seen to obliterate on repeat imaging performed hours later. This "redistribution" phenomenon is thought to reflect the equilibration of myocardial blood flow between transiently ischemic and nonischemic myocardial segments occurring in the postexercise period.[3] This equilibration would not be expected to occur between normal and scarred myocardial segments, suggesting that thallium redistribution might allow the differentiation of reversibly ischemic from irreversibly infarcted myocardium.[3]

The mechanism of thallium redistribution is incompletely understood. Myocardial thallium concentration early after injection of the isotope is dependent to a large extent on myocardial blood flow.[3,4] However, it is less clear to what extent factors other than blood flow might affect regional thallium concentration measured hours after injection. In this study we examined the relation between thallium distribution and regional myocardial blood flow in dogs after 2 hours of continuous myocardial ischemia to test the hypothesis that thallium redistribution into an ischemic region may not depend solely on restoration of blood flow. The data suggest that a significant component of thallium redistribution may be flow-independent.

Methods

Experimental procedure: Twelve mongrel dogs (20 to 25 kg) were anesthetized with sodium pentobarbital (20 mg/kg body weight). A left thoracotomy was performed and the heart suspended in a pericardial cradle. The left circumflex coronary artery was dissected free and an electromagnetic flow probe (Biotronix) placed around it. A variable screw occluder was placed around the circumflex coronary artery just distal to the flow probe (Fig. 1). A catheter was placed in the left atrium for the injection of radioactive microspheres. Catheters were placed in both femoral arteries for withdrawal of blood samples during microsphere injection and for monitoring arterial blood pressure. Microspheres, (7 to 10 μ diameter, labeled with either niobium-95 or scandium-46) were used to determine myocardial blood flow.

Protocol: Two different protocols were used, with six dogs in each (Fig. 2). In all 12 dogs the variable occluder was adjusted just enough to abolish the reactive hyperemic response to a 10 second occlusion of the left circumflex coronary artery. The dogs then underwent pacing, with use of an atrial electrode, to a heart rate of approximately 220 beats/min. After 10 minutes of pacing an injection of 3×10^6 radioactive microspheres was made and followed immediately by an injection of 200 μCi of thallium-201. In 6 of these 12 dogs (group I) atrial pacing was maintained for an additional 10 minute period, after which the heart was excised. In the remaining six dogs (group II) atrial pacing was maintained for an additional 2 hours after thallium injection before a second injection of microspheres was made and the heart was excised.

Just before excision of the hearts methylene blue was injected into the left circumflex coronary artery near the site of stenosis. This injection allowed the left ventricular free wall to be divided into a stained circumflex-perfused ischemic zone and an unstained nonischemic zone perfused by the left anterior descending coronary artery. Multiple transmural samples (range 2 to 5 g) were taken from the ischemic and nonischemic zones as well as from the border zone formed by the boundary between stained and unstained myocardium. These samples were then cut into endocardial and epicardial halves. The activity levels of each tissue sample were determined in a well scintillation counter. The relative activity levels per gram of myocardium contributed by thallium-201, niobium-95 and scandium-46 were determined with computer techniques.

Analysis of the data: First, in both groups I and II, the thallium and microsphere activity levels of samples taken from ischemic and border zone myocardium were normalized by dividing these values by the corresponding mean nonischemic zone activity levels. Second, the normalized ischemic zone microsphere activity levels of samples taken from groups I and II after 10 minutes of pacing were compared using the unpaired t test. Then, in group II, the normalized microsphere activity levels of ischemic and border zone samples obtained after 10 minutes of pacing were compared with the normalized activity levels after 2 hours of pacing using the paired t test. Finally, the relation between normalized thallium activity and normalized microsphere activity was determined for ischemic and border zone samples within each group and the two groups were compared. Individual samples were grouped according to their normalized microsphere activity measured after 10 minutes of pacing (0.0 to 0.39, 0.4 to 0.59, 0.6 to 0.79 and 0.8 to 1.0) and average normalized thallium activity levels were computed for each microsphere range. The four mean thallium activity levels in group I (10 minutes of pacing) were compared with the respective mean activity levels in group II (2 hours of pacing) using the unpaired t test.

Results

Heart rate and blood pressure: A total of 12 dogs were studied with 6 dogs in each group. The data are expressed as mean ± standard error of the mean. Atrial pacing increased heart rate from 144 ± 10 to 215 ± 6 beats/min in group I and from 156 ± 5 to 223 ± 3 beats/min in group II. In group I pacing was associated with an increase in mean left atrial pressure from 5 ± 1.7 to 9 ± 3 mm Hg (p [probability] <0.05) and a slight decrease in mean arterial blood pressure from 111 ± 8 to 108 ± 14 mm Hg (NS [not significant]). In group II mean left atrial pressure increased from 4 ± 2.0 to 13 ± 2 mm Hg ($p < 0.05$) and mean arterial pressure decreased from 119 ± 9 to 110 ± 10 mm Hg (NS).

Endocardial and epicardial flow in nonischemic zone: During pacing, the mean endocardial flow in the nonischemic zone in group I was 135 ± 29 ml/min per 100 g and the mean epicardial flow 131 ± 38 ml/min per 100 g. In group II the mean endocardial flow in the

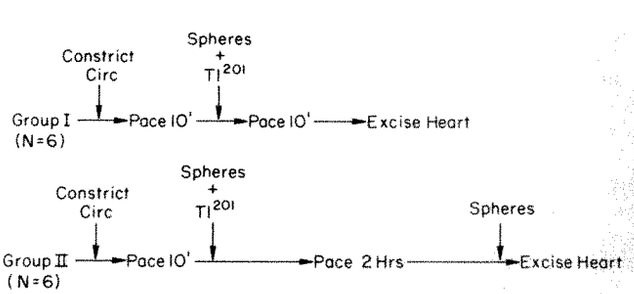

FIGURE 2. Diagram of protocol used in dogs in groups I and II. Circ. = left circumflex coronary artery.

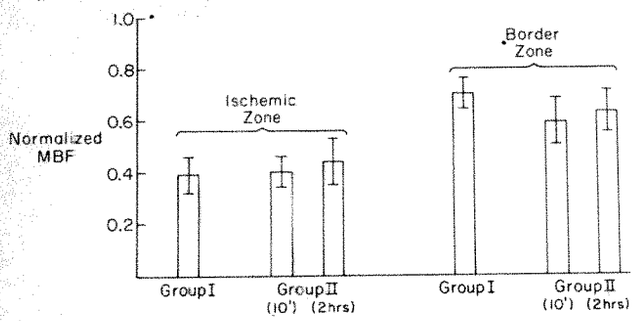

FIGURE 3. Mean normalized endocardial blood flows (MBF) in ischemic and border zones, measured after 10 minutes and 2 hours of pacing, in dogs in groups I and II. In group II reduction in flow in the ischemic zone persisted throughout the 2 hour pacing period.

nonischemic zone was 155 ± 40 ml/min per 100 g and the mean epicardial flow 154 ± 36 ml/min per 100 g after 10 minutes of pacing. The differences between groups I and II at 10 minutes were not statistically significant. After 2 hours of pacing, the mean endocardial flow in the nonischemic zone decreased in group II to 117 ± 21 ml/min per 100 g and the mean epicardial flow to 122 ± 18 ml/min per 100 g; neither change was statistically significant ($t = 1.804$ and 1.267, respectively, with 5 df [degrees of freedom]).

Endocardial and epicardial flow in ischemic zone: During atrial pacing, relative endocardial flow was reduced in the central ischemic zone to 0.39 ± 0.07 in group I and to 0.40 ± 0.06 in group II compared with flow in the nonischemic zone (Fig. 3). In the border zones, relative endocardial flow was 0.70 ± 0.06 in group I and 0.59 ± 0.09 in group II. Epicardial blood flow in the ischemic and nonischemic zones in groups I and II was not significantly different during pacing (Fig. 4). Thus, atrial pacing for 10 minutes in the presence of a flow-limiting coronary stenosis produced a predominantly endocardial reduction in blood flow with little change occurring in epicardial flow. The reduction in flow with pacing relative to flow levels in the nonischemic zone were comparable in groups I and II.

In group II, the mean normalized endocardial flow in the ischemic zone measured after 10 minutes of pacing (0.40 ± 0.06) did not differ from the flow measured at 2 hours (0.44 ± 0.09) ($p > 0.05$). Similarly, normalized endocardial flow in the border zone at 10 minutes (0.59 ± 0.09) was comparable to the flow after 2 hours of pacing (0.63 ± 0.08) ($p > 0.05$). Relative epicardial flows in ischemic and border zone myocardium also did not change significantly over the 2 hour period of pacing. In absolute terms, because flow in the nonischemic zone decreased slightly over the 2 hour period (NS), absolute flows to the endocardial and epicardial halves of the ischemic and border zones also decreased slightly in a proportional manner (NS).

Thallium activity versus blood flow: The mean normalized thallium activity levels obtained by grouping the individual activity levels of samples with similar normalized flows after 10 minutes of pacing were significantly greater in dogs in group II with 2 hours of pacing than in dogs in group I with 10 minutes of pacing (Fig. 5). For the flow range of 0.0 to 0.39 (mean flow 0.25 ± 0.02) the mean normalized thallium activity was 0.50 ± 0.07 in group II compared with 0.33 ± 0.03 in group I ($p < 0.05$). Over the range of 0.4 to 0.59 (mean flow 0.50 ± 0.03) the mean thallium activity was 0.76 ± 0.05 in group II compared with 0.62 ± 0.03 in group I ($p < 0.05$). Over the range of 0.6 to 0.79 (mean flow 0.70 ± 0.01) the thallium activity was 0.86 ± 0.02 in group II compared with 0.77 ± 0.02 in group I ($p < 0.05$). The mean normalized thallium activity levels over the flow range of 0.8 to 1.0 in group II (0.92 ± 0.02) were not significantly different from those in group I (0.92 ± 0.02).

Discussion

Thallium concentration and clearance as a marker for regional myocardial blood flow: The rational use of a radioisotope as an indicator of organ

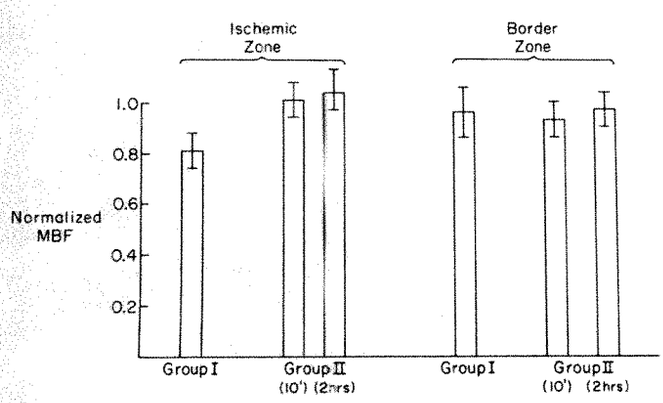

FIGURE 4. Mean normalized epicardial blood flows (MBF) in ischemic and border zones, measured after 10 minutes and 2 hours of pacing, in groups I and II dogs. Note that pacing had similar effects on epicardial flow in both the ischemic and the nonischemic zones.

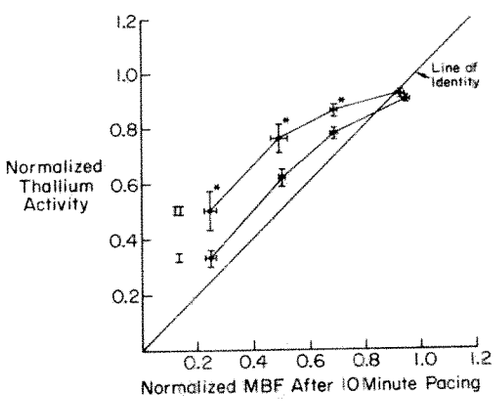

FIGURE 5. Mean normalized thallium concentrations measured after 10 minutes of pacing in group I compared with concentrations measured after 2 hours of pacing in group II. The thallium activity levels measured after 2 hours of pacing (group II) were significantly greater over the myocardial blood flow (MBF) ranges selected than the activity levels measured after 10 minutes of pacing (group I) * = $p < 0.05$.

blood flow depends on a clear understanding of the factors determining the tissue concentration of the isotope as a function of time. When the extraction fraction of an isotope (defined as the difference between the arterial and venous concentrations divided by the arterial concentration) is constant over a range of flows, the clearance (the product of blood flow and extraction fraction) is directly proportional to flow.[5] An isotope with flow-limited clearance would thus be ideal for monitoring regional blood flow because tissue uptake over time would be directly proportional to flow. The extraction fraction of thallium, based on monitoring the single passage of a bolus dose of the isotope through myocardium, appears to be close to 90 percent over a physiologic range of blood flows.[4] On the basis of these first pass properties of thallium the isotope has been accepted as a reasonable noninvasive marker for regional myocardial blood flow.

Thallium redistribution: There are fewer data available concerning the changes in thallium concentration in myocardium over significant time intervals after injection of the bolus dose. It seems reasonable to assume that myocardial thallium concentration over time after injection is a complex function of the first pass uptake of the isotope, the rate of tissue washout and the effects of long-term exposure of myocardial segments to residual low concentrations of recirculating thallium and to changes in flow over time. The redistribution of thallium in the recovery period after exercise is currently believed to be due primarily to a relative increase in thallium uptake by previously ischemic myocardium compared with nonischemic myocardium.[6,7] This interpretation of thallium redistribution places the major emphasis on equilibration of myocardial blood flow as the primary mechanism of redistribution.

A dog preparation employing atrial pacing in the presence of a fixed coronary stenosis was used in this study as a model of exercise-induced angina pectoris in patients with coronary atherosclerosis. Pacing in the presence of a left circumflex arterial stenosis produced a predominantly subendocardial reduction in blood flow to levels 50 percent below the level of flow in the nonischemic zone. Epicardial flow in the ischemic zone during pacing was similar to flow in the nonischemic zone. These flow distributions contrast sharply with the changes in flow produced by ligation in which epicardial flow can drop to levels less than 20 percent of flow values in the nonischemic zone and endocardial flow to levels less than 10 percent of these values.[3] Thus, pacing in the presence of left circumflex arterial stenosis produced a significant mass of myocardium with a less drastic reduction in blood flow compared with that produced by coronary ligation. In the presence of this milder reduction in flow our data indicate that a considerable degree of thallium redistribution can occur over a 2 hour period even when inequality of flow between the ischemic and nonischemic zone is maintained. This suggests the presence of a significant flow-independent component of thallium redistribution.

Mechanism of flow-independent redistribution of thallium: The exact mechanism responsible for this flow-independent redistribution of thallium cannot be determined from our data. The findings only suggest, as others have noted, that in the presence of a predominantly subendocardial reduction in flow a considerable degree of redistribution can occur in the absence of equilibration of flow between the ischemic and nonischemic zones.[8,9] It is possible that the lesser reduction in flow noted with stenosis compared with ligation may interfere less with energy-requiring processes involved in the active transport of thallium and also would allow the ischemic zone to be exposed to more recirculating residual thallium over time. These effects would tend to obliterate the first pass inequality of thallium uptake between the ischemic and nonischemic zones over time and suggest that thallium is redistributed in proportion to the mass of ischemic tissue or to the number of active transport sites in the ischemic zone.

Clinical implications: It is unclear whether our results are directly applicable to clinical thallium scintigraphic studies during exercise. Although our animal model was chosen to simulate changes in myocardial blood flow during exercise, we maintained these changes constant over 2 hours to allow identification of a flow-independent contribution to thallium redistribution, whereas in patients flow is believed to return quickly to baseline levels after exercise is completed. A flow-dependent type of redistribution might therefore predominate after exercise in human subjects. However, it has recently been shown[8] that redistribution into myocardial segments with initially low thallium uptake occurs in some patients at rest, suggesting that a flow-independent process may be important in human subjects under other circumstances. Further study is necessary to clarify those factors other than myocardial blood flow that are important components of the redistribution process.

To evaluate a new method of calculating right ventricular ejection fraction by equilibrium radionuclide angiography and to assess its response during supine bicycle exercise, 20 normal persons and 50 patients with angiographically documented coronary artery disease were studied. Each subject underwent a resting equilibrium and first pass right ventricular study as well as symptom-limited graded bicycle exercise while supine. The correlation between the two methods in all 70 cases was good ($r = 0.81$). Inter- and intraobserver variability was small (3.9 ejection fraction units or less) and serial reproducibility (two studies performed 2 weeks apart) was also good (4 ejection fraction units or less). There was no difference in the right ventricular ejection fraction at rest when normal subjects and patients with coronary disease were compared (0.49 ± 0.10 versus 0.46 ± 0.08). Ejection fraction increased with exercise in normal subjects (0.49 ± 0.10 to 0.64 ± 0.12, $p < 0.005$). As a group, patients with right coronary stenosis (alone or in combination with other lesions) showed no change in ejection fraction with exercise (0.46 ± 0.13 to 0.45 ± 0.12); and ejection fraction increased with exercise in patients with coronary disease without right coronary stenosis (0.46 ± 0.08 to 0.53 ± 0.11, $p < 0.05$). Among patients with both significant right and left coronary artery disease more severe right ventricular dysfunction during exercise was seen in the presence of more severe left ventricular dysfunction. It is concluded that during exercise the right ventricle shows dysfunction caused in part by local ischemia as well as by altered loading conditions due to left ventricular dysfunction. Equilibrium angiography is a useful and reliable method for evaluating right ventricular function in man.

Recently it has become apparent that a small proportion of patients with coronary heart disease exhibit a normal increase in left ventricular ejection fraction during maximal bicycle exercise as assessed by radionuclide angiocardiography.[1,2] Because it is possible that ischemic dysfunction during exercise stress in these patients involves the right rather than the left ventricle, several investigators[3–5] evaluated right ventricular function during bicycle exercise by equilibrium and first pass radionuclide techniques. They found that many subjects with significant obstructive lesions of the right coronary artery showed abnormal right ventricular function during exercise as assessed by the right ventricular ejection fraction. To expand these observations in a larger series of patients and to validate a new method for estimating right ventricular ejection fraction by equilibrium radionuclide angiography, we evaluated 20 normal subjects and 50 patients with coronary heart disease documented by contrast angiography.

Methods

Patient Groups

Group I (20 normal subjects): This group comprised 16 men and 4 women ranging in age from 24 to 52 years (mean ± standard error of the mean 38 ± 6). Five of these patients had normal findings on contrast ventriculography and coronary angiography when they were studied for complaints of atypical chest pain. The other 15 were normal volunteers and met the following criteria for inclusion in the study: (1) normal clinical examination; (2) normal resting and exercise electrocardiogram; (3) no history of hypertension, diabetes or lipid abnormalities; (4) absence of medications and symptomatic complaints; and (5) a normal chest radiograph.

Groups II to V (50 patients with angiographically documented coronary heart disease): These patients were studied for complaints of chest pain and included 36 men and 14 women with an age range of 31 to 72 years (mean 46.5 ± 10). Four patients were taking digoxin daily at the time of study for treatment of chronic congestive heart failure. Thirteen patients had had well documented prior myocardial infarction, defined by a history of prolonged chest pain in the setting of typical serum enzymatic (creatine kinase MB, serum glutamic oxaloacetic transaminase and lactic dehydrogenase) and electrocardiographic evolutionary changes. Contrast angiograms were performed either preoperatively or for the diagnosis and characterization of the severity of coronary artery disease.

To be included in the study these patients had to meet the following criteria: (1) at least one major coronary arterial obstruction with 70 percent or greater intraluminal narrowing; (2) no evidence of valvular heart disease or intracardiac shunts; (3) no recent (within 1 week) use of propranolol, antiarrhythmic drugs, long-acting nitrates or antihypertensive medication; and (4) no intraventricular conduction abnormalities on electrocardiographs.

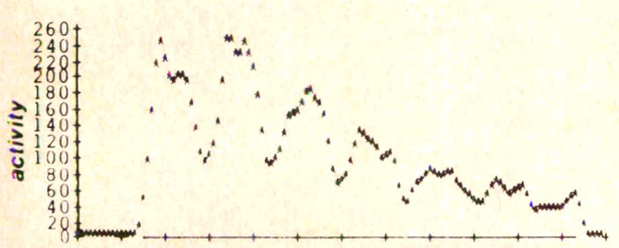

FIGURE 1. Typical right ventricular first transit study performed in the right anterior oblique position. The background-subtracted time-activity curve is utilized to calculate ejection fraction. Bkg = background; PA = pulmonary artery; RA = right atrium; RV = right ventricle.

Data Acquisition and Analysis

First pass radionuclide ejection fraction: All subjects underwent first pass radionuclide angiography in the manner described by Schelbert et al.[6] A brief description of the method follows: An intravenous catheter is placed into an antecubital vein and 15 mCi of technetium-99m-labeled human serum albumin is given as a bolus injection followed by 15 ml of normal saline solution. The patient is supine and the injection follows the positioning of a single crystal mobile scintillation gamma camera detector, which is placed over the thorax in the 30° right anterior oblique position. The camera is equipped with a general purpose low-energy, parallel hole collimator. The data are stored on videotape and then transferred in real time to a dedicated minicomputer system (General Electric Med II Computer System). A light pen program is used for calculation of both left[6] and right[7,8] ventricular ejection fraction. A light pen-assigned region of interest including the right and left ventricle is used to monitor counts at 0.04 second intervals during the transit of the radioactive bolus dose through the respective cardiac chambers. Background correction is made and a curve produced showing the cyclical changes in count rate. For the right ventricle, two to three beats of the high frequency time-activity curve are manually evaluated, using the peak of the curve as the end-diastolic data point and the nadir of the curve as the end-systolic point (Fig. 1).

Equilibrium radionuclide angiography: All patients are studied after intravenous injection and mixing of technetium-99m-labeled human serum albumin. All studies are performed with the scintillation camera detector located in the 45° left anterior oblique position, which includes a 5 to 10° caudal tilt to maximally isolate the left ventricle from the left atrium. A modified V_5 electrocardiographic lead is monitored during the study and is also used by the computer for gating purposes. Equilibrium data are stored on videomagnetic tape as digital pulses and transferred to a minicomputer for calculation of left ventricular ejection fraction (Medical Data Systems—PAD) or right ventricular ejection fraction (General Electric Med II Computer System).

The left ventricular ejection fraction is calculated by dividing each R-R interval into 28 equal frames of variable duration depending on heart rate and then by summing scintigraphic data from multiple cardiac cycles at each corresponding frame to assemble a composite cardiac cycle. Each image frame has a spatial resolution of 64 × 64 channel elements. Each left ventricular time-activity curve is generated using a semiautomatic computer algorithm. The left ventricular region of interest is assigned at end-diastole, and an edge-detection algorithm using simple count rate threshold and the second derivative of each change in pixel to pixel count profile to determine the edge of the left ventricular chamber. The chamber is tracked through each frame of the composite cycle; thus a varying region of interest is utilized. Background is automatically assigned at end-systole and is located lateral to the left ventricle. The background-corrected left ventricular time-activity curve is then produced, and the ejection fraction calculated. This method has been shown to correlate well with contrast ventriculography,[7,9] to be reproducible over time,[10] to correlate well with first pass ejection fractions when both (at separate times) are determined at peak exercise[11] and to be independent of the duration of data acquisition.[9]

Right ventricular ejection fraction is determined from a fixed region of interest assigned at the end-diastolic frame.

Each R-R interval is divided into 24 equal segments and multiple cycles are summed to form a composite cardiac cycle. This acquisition is different from that described for the left ventricular analysis and is due to varying software instructions on the acquisition programs on each computer. The computer acquires six 32 × 32 raw data records, which are then interpolated into twenty-four 64 × 64 records. The data for the 24 records are integrated to form one picture that most resembles the end-diastolic image. The operator then outlines the right ventricle with a light pen, taking care to avoid the pulmonary outflow tract and, when visible, the edge of the right atrium. Background is assigned around the right ventricle in the integrated picture and includes the pulmonary outflow tract but not the interventricular septum. If the right atrium is visible, it is also included into the background. Background is normalized to the end-diastolic area and the activity in the fixed background region is subtracted from each frame to form a corrected time-activity curve. With the aid of two light cursors, the operator selects the peak and valley of the time-activity curve and the ejection fraction is calculated (Fig. 2) using the following equation: Ejection fraction = $(EDC_c - ESC_c)/EDC_c$, where EDC_c = background-corrected end-diastolic counts and ESC_c = background-corrected end-systolic counts. We have previously[12] shown that for calculating right ventricular ejection fraction this is a reproducible method whose results correlate well with those of first pass radionuclide angiograms.

Clinical Protocol

Each patient was studied while supine after the first pass intravenous injection. The single crystal gamma camera detector was relocated in the 45° left anterior oblique position over the thorax with a 5 to 10° caudal tilt to maximize separation of the left ventricle from surrounding structures. Five minutes of electrocardiographically gated scintillation data were collected at rest; additional data collection periods constituted the last 2 minutes of each subsequent 3 minute block of progressively strenuous supine bicycle exercise. After

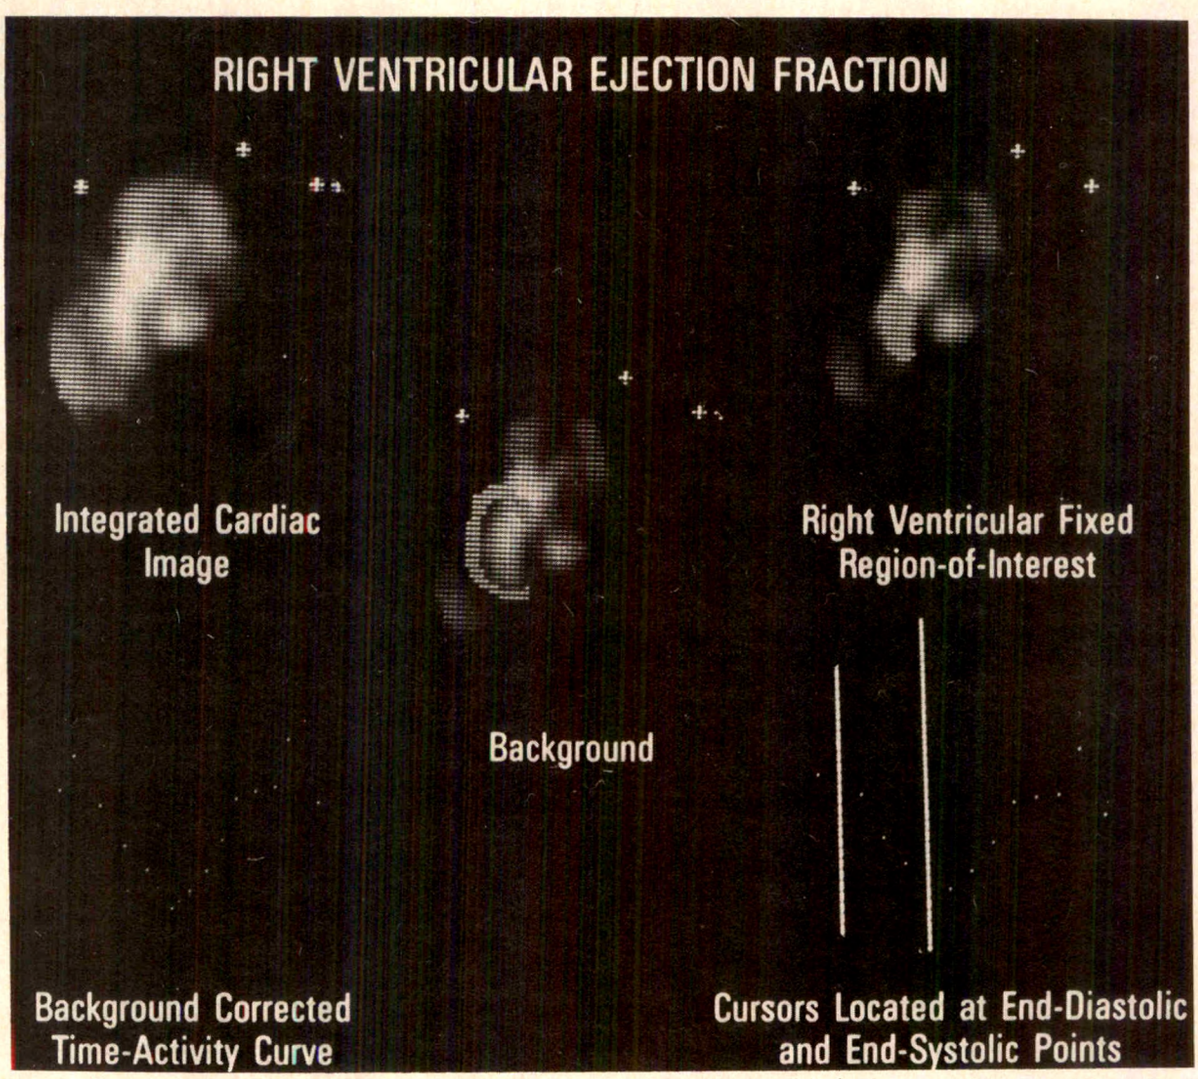

FIGURE 2. Process of calculating the right ventricular ejection fraction with the equilibrium method. The summed (integrated) image is at **upper left.** The light-penned right ventricular region of interest and background region of interest are shown with the background-corrected time-activity curve. The operator locates the peak (end-diastolic point) and nadir (end-systolic point) of the time-activity curve with two cursors, and the ejection fraction is calculated using these two points.

each 3 minute stage was completed, an additional work load was added until fatigue or pain resulted. Exercise was discontinued if the patient complained of angina or severe fatigue or if marked electrocardiographic abnormalities occurred (S-T segment depression greater than 5 mV). A modified V_5 lead was used to monitor the electrocardiogram. Heart rate and blood pressure were recorded at rest and at peak exercise. No patients had more than three ectopic beats per minute at rest or peak exercise.

Reproducibility: (1) All 70 subjects had both a first pass and equilibrium right ventricular ejection fraction calculated by two observers unaware of each other's calculations. (2) All 70 resting equilibrium right ventricular ejection fractions were then calculated by one observer on two occasions separated by at least 2 months. (3) The resting equilibrium right ventricular ejection fractions were calculated by a second observer in 25 randomly selected cases. This observer had no knowledge of the results of the first observer. (4) Fifteen patients underwent two equilibrium studies within 3 weeks (mean 14.5 ± 3 days) for evaluation of reproducibility over time. (5) Fifteen studies were randomly selected and were evaluated on three occasions, using 2, 3 or 5 minutes of equilibrium (real-time) scintigraphic data.

Statistical analyses: All regression lines and correlation coefficients were developed using a least-squares fit. Data were evaluated by means of Student's *t* test for paired and unpaired data and, when appropriate, a repeated measures analysis of variance.[13]

Results

Vital Signs

There were no significant differences between the values at rest for heart rate, systolic blood pressure or diastolic blood pressure when the normal subjects and the patients with coronary heart disease were compared (76.4 ± 12.2 versus 78.3 ± 13.4 beats/min; 128.2 ± 14.6 versus 124.5 ± 18.4 mm Hg and 74.4 ± 16 versus 78.6 ± 12 mm Hg, respectively; all $p > 0.05$).

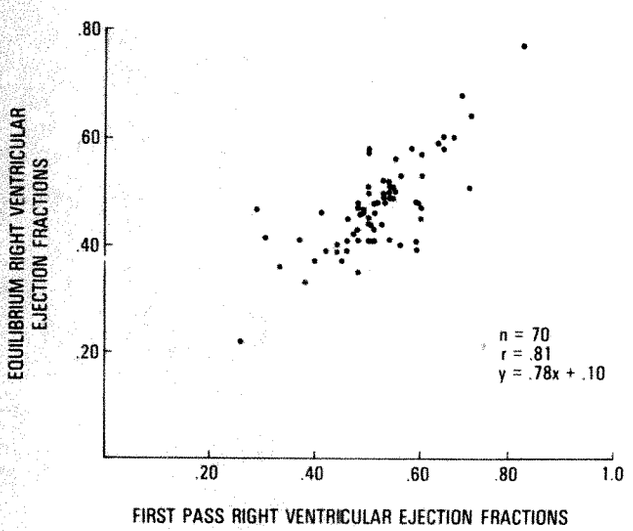

FIGURE 3. Correlations between first pass and equilibrium radionuclide right ventricular ejection fractions are shown for all 70 cases (20 normal subjects and 50 patients with coronary artery disease).

The normal subjects exercised to a higher work load than did the patients with coronary disease (950 ± 220 versus 435 ± 210 kpm, $p < 0.01$) as well as to a higher pressure-rate (double) product (24,364 ± 4,000 versus 17,600 ± 7,000, $p < 0.005$).

All normal subjects and 28 of the 50 patients stopped exercising because of complaints of fatigue, whereas 22 of the 50 patients stopped exercising because of complaints of chest pain associated with S-T segment depression greater than 0.1 mV on the V_5 monitor lead.

Right Ventricular Ejection Fraction

First-pass and equilibrium correlation: The mean right ventricular ejection fraction at rest determined with first pass angiography was 0.53 ± 0.09, a value higher than the mean result calculated with the equilibrium method (0.49 ± 0.10, $p < 0.01$). The correlation between the two methods was good over a broad range of ejection fraction values ($r = 0.81$) (Fig. 3).

Right ventricular response: *Normal subjects (Table I):* In 19 of 20 normal subjects the right ventricular ejection fraction increased by 13 percent or more (absolute percent, not ejection fraction units) when compared with the resting value (Fig. 4). One subject had no change during exercise (0.43 at rest and during peak exercise). The mean right ventricular ejection fraction in this group was 0.49 ± 0.10 and rose significantly to 0.64 ± 0.12 at peak exercise ($p < 0.005$).

Patients with coronary artery disease: The mean resting right ventricular ejection fraction in the patients

* $p < 0.005$.

with coronary artery disease was 0.46 ± 0.08; this value was lower than that in the normal patients, but the difference did not attain statistical significance ($p = 0.07$). Peak exercise right ventricular ejection fractions averaged 0.50 ± 0.13, a value higher than that at rest ($p < 0.05$) but lower than the peak exercise value in the normal subjects ($p < 0.01$).

Relation between coronary lesions and right ventricular ejection fraction response (Table II): *Group II: Six patients with isolated right coronary artery disease:* The mean resting right ventricular ejection fraction in this group was 0.51 ± 0.06 and decreased to 0.42 ± 0.15 at peak exercise ($p < 0.05$) (Fig. 4). Four patients had decreases of 13, 17, 16 and 13 ejection fraction units, respectively, with exercise, in association with complaints of chest pain. These four had a normal resting left ventricular ejection fraction and a normal left ventricular response to exercise (increase of 10 percent or more above resting left ventricular ejection fraction). One patient showed no change in right ventricular ejection fraction with exercise and one had a 10 percent increase (5 ejection fraction units). Each of these latter two patients had an abnormal left ventricular response. The patient with a normal right ventricular response had had a previous subendocardial myocardial infarction.

Group III: Thirteen patients with a combination of right and left anterior descending coronary artery disease: No subject in this group had a normal left ventricular response to exercise (Fig. 4). Mean right ventricular ejection fraction at rest was 0.49 ± 0.07, a value not significantly different from the value at peak exercise (0.48 ± 0.13). Six patients had a decline in right ventricular ejection fraction with exercise, and eight had less than a 10 percent increase. Four patients in this group had had a previous infarction (anterior in two and inferior in two). One patient with an anterior and one with an inferior infarction had an increase in ejection fraction with exercise; the remaining two patients had a decrease.

Group IV: Nineteen patients with three vessel coronary artery disease: No subject in this group had a normal left ventricular response to exercise (Fig. 4). The mean right ventricular ejection fraction at rest was 0.44 ± 0.10 and the peak exercise ejection fraction 0.46 ± 0.14, not significantly different from the resting value. Nine patients had less than a 10 percent increase in right ventricular ejection fraction with exercise, and six actually had a decrease in ejection fraction. Five patients in this group had had a previous infarction (inferior in three and anterior in two). Again the right ventricular response varied in these patients, increasing in one patient with an anterior infarct, decreasing in one patient with an anterior and in one with an inferior infarct, and not changing in two patients with a previous inferior infarct.

Group V: Twelve patients with isolated left anterior descending coronary artery disease or combined left anterior descending and left circumflex coronary artery disease: Five of these 12 patients had isolated left anterior descending coronary artery disease and 7 had double vessel disease. All patients in this group had an

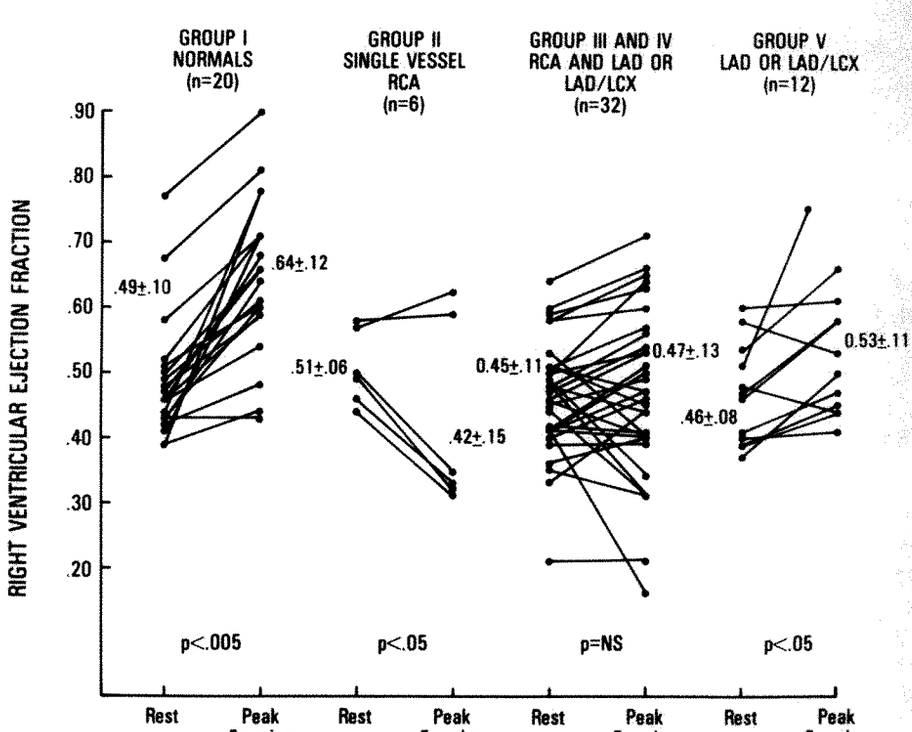

FIGURE 4. Results of the equilibrium right ventricular ejection fraction are plotted at rest and during exercise in Group I, Group II, Groups III and IV combined and Group V. LAD = left anterior descending coronary artery; LCx = left circumflex coronary artery; RCA = right coronary artery.

abnormal left ventricular response to exercise (Fig. 4). The mean resting right ventricular ejection fraction was 0.49 ± 0.07, which was not different from that of any of the previous three subgroups of patients. Peak exercise ejection fraction was increased (0.53 ± 0.11, $p < 0.05$). Only two patients had a decrease in ejection fraction with exercise, and only four had an increase of less than 10 percent with exercise; thus, significantly fewer patients in this group had an abnormal right ventricular response to exercise ($p < 0.05$). Two of these four patients with an abnormal response had had a previous myocardial infarction (anterior and subendocardial, respectively, as determined with electrocardiographic criteria) and the other two had small right coronary arteries with disease of a "dominant" left coronary system that supplied collateral flow to the right ventricle.

Reproducibility: (1) The intraobserver variability was 3.2 ± 3 (mean ± 1 standard deviation) ejection fraction units when all 70 studies were reevaluated (separated by a time period of at least 2 months). (2) The interobserver variability was 3.9 ± 2.9 ejection fraction units in 25 randomly selected patients. (3) When 15 patients were reevaluated a mean of 14.5 ± 3 days after the initial study, the mean variation between the two studies was 4 ± 2.1 ejection fraction units (range 0 to 7 units). (4) Finally, 15 studies were randomly selected and processed for 2, 3, and 5 minutes of scintigraphic data. Right ventricular ejection fraction studies were performed for each of these three data acquisition times and compared. For this study, mean variation in ejection fraction was 3.8 ± 2 ejection fraction units.

Left Ventricular Ejection Fraction

Normal subjects: All normal subjects had an increase in left ventricular ejection fraction of 10 percent or more (absolute percent not ejection fraction units). Mean resting left ventricular ejection fraction was 0.61 ± 0.06 and increased to 0.75 ± 0.09 at peak exercise ($p < 0.005$).

Patients with coronary artery disease: All patients with significant atherosclerotic involvement (70 percent stenosis or greater) of a major branch of the left coronary artery had an abnormal left ventricular response to exercise (defined as an increase of less than 10 percent in left ventricular ejection fraction with exercise). Of the six patients with single vessel right coronary artery disease, four had a "normal" increase in left ventricular ejection fraction. These four with a "normal" response had a reduction of 17, 35, 32 and 28 percent (absolute percent), respectively, in right ventricular ejection fraction during exercise. They each had a proximal occlusion (70, 85, 90 and 90 percent, respectively) of the right coronary artery with good collateral flow to the apex of the left ventricle from the left circumflex artery. The other two patients had an occlusion of 70 and 75 percent, respectively, at the junction of the posterior descending artery. In these patients the left ventricular ejection fraction response was abnormal (+4 and −6 percent change with exercise, respectively). The right ventricular response was abnormal in one case (+2 percent) and normal in the other (+10 percent). In the latter case, the left circumflex artery supplied collateral flow to the right ventricle.

When the left ventricular response in the patients with significant right coronary artery disease was evaluated, the patients with an associated abnormal right ventricular response had a poorer left ventricular response (−4.4 ± 7 percent change with exercise) when compared with the group with a normal right ventricular response (−2.9 ± 8 percent, $p = 0.08$), although this difference did not attain statistical significance. When the patients with single vessel right coronary artery disease were excluded, the relationship was reversed. The patients with a normal right ventricular response had a better left ventricular response (−0.97 ± 6 versus −3.3 ± 7 percent change with exercise, $p = 0.04$). Angina developed in 8 of the 21 patients with an abnormal right ventricular response, and in 8 of 17 patients with a normal right ventricular response.

In the group without significant right coronary stenosis, the eight patients with a normal right ventricular response had an exercise change in left ventricular ejection fraction of −6.1 ± 7.3 percent compared with −8.2 ± 8.1 percent in the four patients with an abnormal right ventricular response. Angina developed in three patients in each group. These differences were not statistically different, although the number of patients was limited.

Discussion

Recent descriptions of the response of the left ventricle to exercise stress[14–16] have stimulated renewed interest in right ventricular function during exercise.[3–5] It has become increasingly clear that right ventricular dysfunction can occur without left ventricular dysfunction in the setting of acute myocardial infarction[7,17] and that this probably relates to the location of the coronary arterial lesion and the site of infarction.[18] Thus, whereas right ventricular dysfunction from an acute ischemic insult now appears firmly proved, transient dysfunction from stress-induced imbalances in oxygen delivery and oxygen requirements has only recently been recognized.[3–5]

To extend these studies and to introduce a new method for evaluating right ventricular function, we studied 70 persons with both first pass and equilibrium radionuclide angiography. The correlation between the two techniques was good ($r = 0.81$) over a wide range of ejection fractions. Inter- and intraobserver variability was modest (less than 4 ejection fraction units) as was the variability over time (4 ejection fraction units or less).

Right ventricular ejection fraction in normal subjects during exercise: Nineteen of 20 normal subjects had a greater than 10 percent increase in right ventricular ejection fraction with exercise. The single exception was one subject who showed no change with exercise. The stress electrocardiogram, left ventricular

response to exercise, chest roentgenogram and physical examination were all normal, and he had no evidence (by radionuclide methods) of an intracardiac shunt.

Effect of right coronary artery disease on right ventricular function: In general, the presence of a significant right coronary arterial lesion increased the likelihood of an abnormal right ventricular response to exercise. In patients with single vessel right coronary artery disease, the more severely abnormal the right ventricular response, the more "normal" the left ventricular response. As previously mentioned, in four patients with single vessel right coronary artery disease a *severe* exercise-induced reduction in right ventricular ejection fraction was associated with a normal increase in left ventricular ejection fraction. In addition, these patients had lesions in coronary arteries that predominantly supplied the right ventricle. In contrast, two patients with single vessel right coronary artery disease had a more "normal" right ventricular response, one had an increase in right ventricular ejection fraction of 2 percent and the other had an increase of 10 percent (absolute percent, not ejection fraction units) but an abnormal left ventricular response. The stenotic coronary artery in these patients appeared to supply a portion of the left ventricular apex.

In the patients with both right and left coronary artery disease, 17 of 32 (53 percent) had a less than 10 percent increase in right ventricular ejection fraction with exercise, whereas all 32 had an abnormal left ventricular response. This finding may suggest that multiple vessels can be involved in causing ventricular dysfunction with exercise or that the right coronary artery can be the cause of both right and left ventricular stress-induced dysfunction.

The causes of ventricular dysfunction after exercise: A variety of other physiologic phenomena must undoubtedly play some part in the explanation of biventricular dysfunction. In severe stress-induced left ventricular dysfunction, severe left ventricular dilatation may develop in some patients[16] in association with depressed left ventricular stroke volume[16] and increased left ventricular filling pressure. Undoubtedly, acute changes in left ventricular shape and function must produce alterations in right ventricular performance, just as the right ventricle has been shown to influence the left ventricle.[19–22] Additionally, elevations in pulmonary pressures due to left ventricular dysfunction must impede right ventricular ejection. Acute pressure overload of the right ventricle has been shown to cause right ventricular dysfunction and dilatation and tricuspid regurgitation.[22] Finally, a decrease in stroke volume and cardiac output may decrease right ventricular preload. These theoretical possibilities for the relation between right and left ventricular dysfunction in patients with both right and left coronary stenoses may at least contribute to the present observations.

Effect of left coronary artery disease on right ventricular function: In the patients with left coronary disease (either isolated anterior descending or combined anterior descending and circumflex artery disease), right ventricular function is normal during exercise unless a previous infarction has occurred or the left circumflex artery supplies part of the blood supply to the right ventricle.

Possible limitations of equilibrium radionuclide angiography: There are several theoretical limitations to the calculation of right ventricular ejection fraction with this equilibrium method. The right atrium is located posterior and somewhat lateral to the right ventricle in the left anterior oblique position. Thus, the right atrium is difficult to exclude in this projection when the right ventricular region of interest is assigned. In this study we evaluated no patient with tricuspid regurgitation and obvious right atrial enlargement. Additional limitations include the difficulty in separating the pulmonary outflow tract from the body of the right ventricle and the fact that part of the right ventricle must wrap slightly around the left ventricle in this projection. These theoretical limitations would tend to lower the ejection fraction. This is seen in the lower mean equilibrium right ventricular ejection fraction when compared with the virtually simultaneous first pass ejection fraction.

Some of these problems also apply to the left ventricle when fixed region of interest analyses are performed. For example, the left atrium is difficult to separate from the left ventricle, even with a significant caudal tilt. Yet excellent correlations with contrast ventriculography have been found when left ventricular ejection fraction is calculated with equilibrium angiography. In another study we found that the left atrial activity in a patient with severe mitral regurgitation caused a significant overestimation of left ventricular end-diastolic and end-systolic volumes[23] that did not occur in normal subjects with a normal left atrium. Whereas the left ventricular outflow tract generally presents few difficulties, the right ventricle still must wrap around the left ventricle in this projection, yet it does not seem to contain enough activity to distort the left ventricular calculations.

In this study the correlation between first pass and equilibrium right ventricular ejection fractions was good ($r = 0.81$). Part of the discrepancy between the two methods may rest not only with the equilibrium technique, but also with the statistical variability of the first pass method. Usually one to three beats were manually averaged from a 5 point smoothing of the raw data curve. The variability of these results may range from 6 to 12 ejection fraction units.[7]

Implications: Despite these theoretical limitations our study suggests that stenotic right coronary arterial lesions can cause or contribute to right ventricular dysfunction during exercise. Equilibrium radionuclide angiography can uncover potential right coronary arterial lesions by the serial evaluation of right ventricular function during supine bicycle exercise. In addition, this method of evaluating right ventricular ejection fraction may prove to be of value in the assessment of pharmacologic and physiologic interventions in a variety of patient populations.

Complete Abolition of the Reentrant Supraventricular Tachycardia Zone Using a New Modality of Cardiac Pacing With Simultaneous Atrioventricular Stimulation

RUEY J. SUNG, MD, FACC

In an attempt to prevent recurrent reentrant supraventricular tachycardia, an experimentally designed new pacemaker has been developed. The pacemaker, when connected to both atrial and ventricular electrodes, is capable of sensing either an atrial or ventricular signal and, in turn, triggers simultaneous atrioventricular (A-V) stimulation. Efficacy of this pacemaker was tested in four patients with recurrent paroxysmal A-V nodal reentrant tachycardia during electrophysiologic studies. After connection of the electrodes to the new pacemaker, all atrial or ventricular premature stimuli elicited simultaneous A-V stimulation with resultant impulse collision in the A-V junction. Consequently, the reentrant tachycardia zone was completely abolished in all patients. This study has thus demonstrated the clinical feasibility of simultaneous A-V pacing to abolish the supraventricular tachycardia zone in man.

Pacemaker therapy is a clinical alternative in the treatment of recurrent supraventricular tachycardia refractory to medical management.[1–6] In most instances, pacemaker therapy is utilized to deliver electric stimuli during tachycardia to interrupt the tachycardia circuit or to render the atrioventricular (A-V) node refractory, thereby slowing the ventricular response.

This communication introduces a new modality of cardiac pacing: simultaneous A-V stimulation that can be utilized to abolish the tachycardia zone in patients with paroxysmal A-V nodal reentrant tachycardia.

Methods

Patients: Four patients with recurrent paroxysmal supraventricular tachycardia who had previously failed to respond to at least two medications constituted the study group. There were three men and one woman ranging in age from 32 to 63 years. After informed consent was obtained, all cardiotonic and antiarrhythmic medications were discontinued 48 to 72 hours before the study.

Electrophysiologic study: The study was performed with the patients in a postabsorptive, nonsedated state. With a conventional technique,[7] the His bundle electrogram was obtained with a tripolar electrode catheter placed across the tricuspid valve, from which low septal right atrial activity was recorded as well. A hexapolar electrode catheter was introduced by way of an antecubital vein; the distal pair of electrodes was placed in the right ventricle, and the proximal two pairs were placed in the high right atrium (HRA). Additionally, two bipolar electrode catheters were inserted and placed in the high right atrium and the right ventricle, respectively, for the purpose of pacing and delivering premature stimuli.

The electrophysiologic study, as previously described,[8] consisted of programmed atrial and ventricular extrastimulation. The high right atrium and the right ventricular endocardium were stimulated at one or two cycle lengths (A_1-A_1 and V_1-V_1), respectively, with the use of a programmed digital stimulator (Biocelestronix, Miami Springs, Florida) that delivered stimuli (S_1 and S_2) of 2 ms duration at approximately twice diastolic threshold. After every eighth spontaneous or paced beat (A_1 or V_1), a single premature atrial or ventricular beat (A_2 or V_2) was delivered at progressively shorter coupling intervals (A_1-A_2 or V_1-V_2) until the effective refractory period of the atrium or the ventricle was encountered.

A-V pacemaker: After the foregoing study protocol was completed, one high right atrial electrode and one right ventricular electrode of the hexapolar electrode catheter were selected for connection to an experimentally designed pacemaker (DDT) (Fig. 1).[9] (The experimental pacemaker was constructed by Barough V. Berkovits, EE, of Medtronics, Inc., Minneapolis, Minnesota.) Adequacy of atrial and ventricular capture was tested several times for proper selection of the atrial and ventricular electrodes. When connected to both the atrial and ventricular electrodes, the pacemaker is capable of sensing either an atrial or a ventricular signal and in turn triggers simultaneous A-V stimulation. It has a refractory period of 260 ms and an escape interval of 800 ms (75 beats/min). Programmed atrial and ventricular extrastimulation, as described earlier, was then repeated to evaluate the efficacy of the pacemaker in controlling the initiation of reentrant supraventricular tachycardia in each patient.

Results

Control observations: Before the atrial and ventricular electrodes were connected to the experimental pacemaker, electrophysiologic studies revealed that all four patients manifested A-V nodal reentry associated with dual A-V nodal pathway conduction as the underlying mechanism of the paroxysmal supraventricular tachycardia. Their pertinent electrophysiologic findings are listed in Table I. Characteristically, discontinuous A-V nodal conduction curves (A_1-A_2, H_1-H_2 and A_1-A_2, A_2-H_2) were generated with programmed atrial extrastimulation, and A-V nodal reentry occurred after achievement of a critical A-V nodal conduction delay (the A-H interval). The A-V nodal reentrant tachycardia utilized a slow A-V nodal pathway for anterograde conduction and a fast A-V nodal pathway for retrograde conduction. During programmed ventricular extrastimulation, all four patients demonstrated progressive prolongation of ventriculoatrial (V-A) conduction (V_2-A_2) as the ventricular premature coupling interval (V_1-V_2) gradually shortened. The corresponding V-A conduction curves (V_1-V_2, A_1-A_2 and V_1-V_2, V_2-A_2) were consistent with retrograde conduction by way of the A-V node—His-Purkinje system. However, ventricular extrastimulation at all premature

2	700	390	280	390–290	0
3	740	410	<290	380–290	0
4	600	370	260	360–270	0

A = after connection to new pacemaker; AERP = anterograde effective refractory period; B = before connection to new pacemaker; DCL = driving cycle length; FP = fast A-V nodal pathway; RT = A-V nodal reentrant tachycardia; SP = slow A-V nodal pathway.

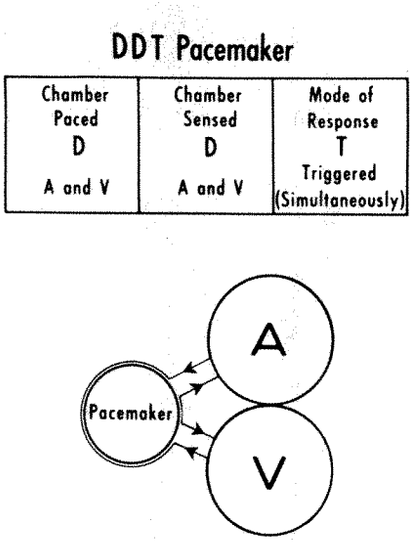

FIGURE 1. Schematic presentation of the new modality of cardiac pacing (DDT)—simultaneous atrioventricular stimulation triggered by either an atrial or ventricular signal. A = atrium; D = dual chambers (the atrium and the ventricle); T = triggered; V = ventricle.

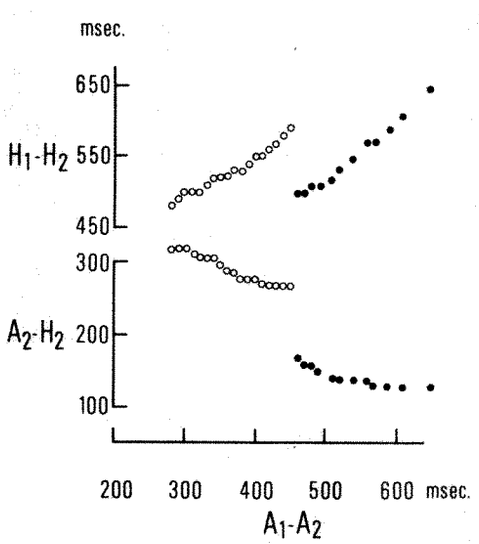

FIGURE 2. Case 1. Dual atrioventricular (A-V) nodal pathway conduction curves (A_1-A_2, H_1-H_2 and A_1-A_2, A_2-H_2) generated during high right atrial pacing at a cycle length of 650 ms. Note the discontinuity of the curves due to the sudden increase in A-V nodal conduction time (A_2-H_2) at an atrial premature coupling interval (A_1-A_2) of 450 ms. Responses are seen with (**open circles**) and without (**solid circles**) initiation of an atrial echo or A-V nodal reentrant tachycardia. For discussion, see text.

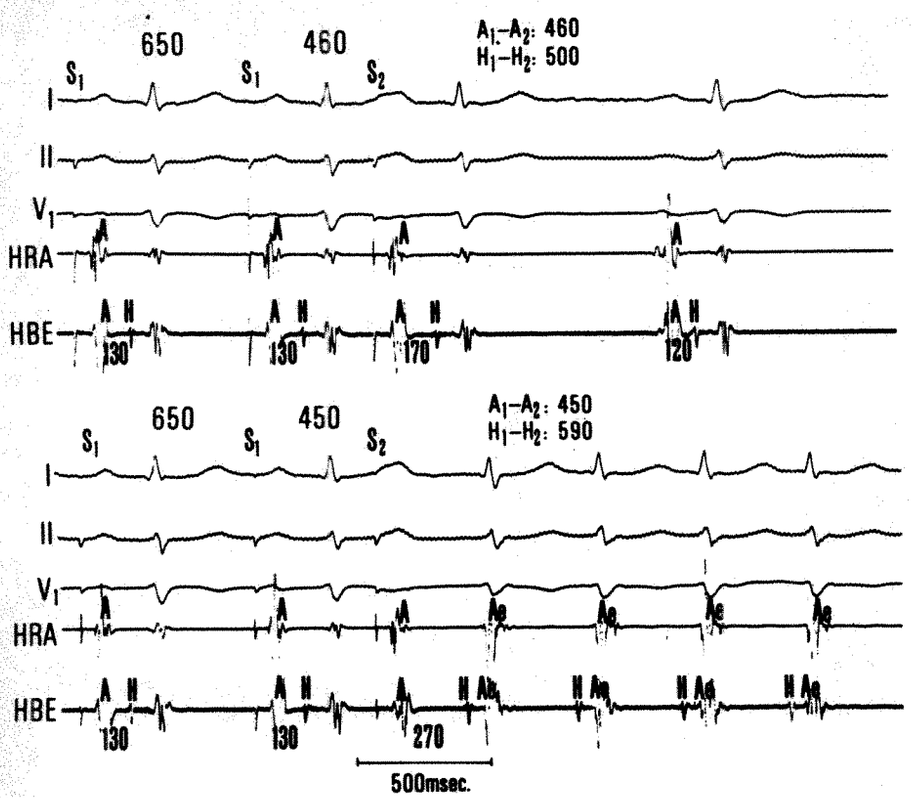

FIGURE 3. Case 1. Atrial premature stimulation with induction of discontinuous atrioventricular (A-V) nodal conduction curves (A_1-A_2, H_1-H_2) followed by initiation of A-V nodal reentrant tachycardia. S_1 and S_2 are pacing and premature stimuli. HRA and HBE are the high right atrial and His bundle electrogram, respectively. Ae indicates the occurrence of atrial echo or atrial reentrant phenomenon. The high right atrium is driven at a cycle length (S_1-S_1) of 650 ms. **Top**, atrial premature stimulus at a coupling interval of 460 ms lengthens A-V nodal conduction time (A-H) from 130 to 170 ms. **Bottom,** atrial premature stimulus at a coupling interval (S_1-S_2) of 450 ms suddenly prolongs A-V nodal conduction time (A-H) to 270 ms, resulting in discontinuous A-V nodal conduction curves (A_1-A_2, H_1-H_2, Fig. 2). This is followed by induction of a sustained A-V nodal reentrant tachycardia. Retrograde atrial activation (Ae) coincides with ventricular depolarization (the QRS complex) during tachycardia.

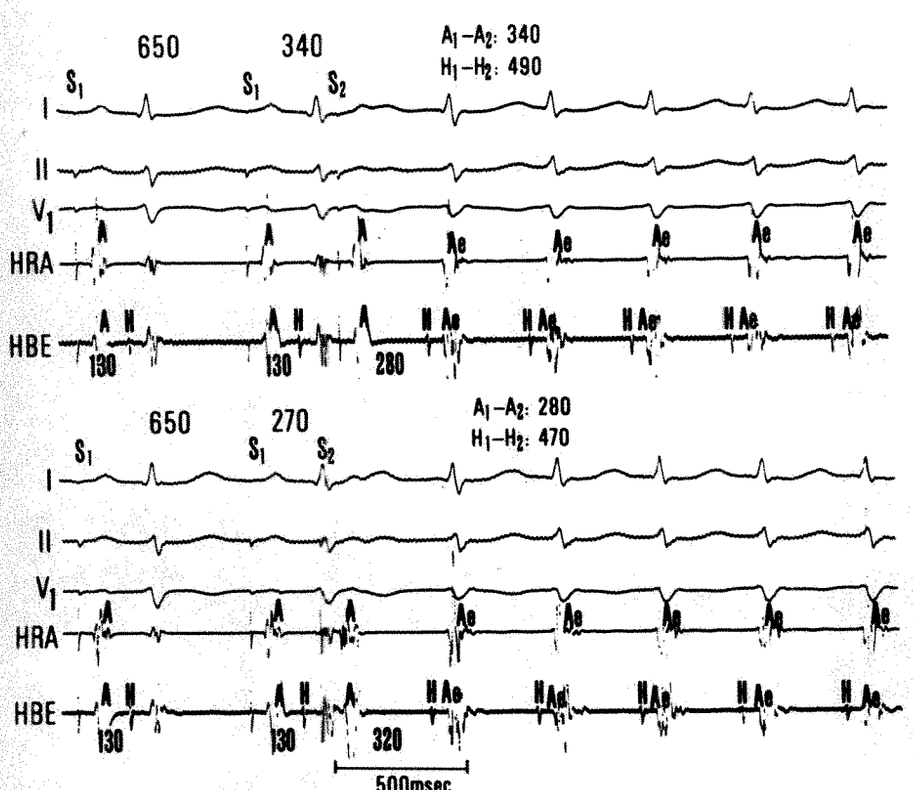

FIGURE 4. Same patient. Progressive atrial premature stimulation continues to elicit paroxysms of atrioventricular (A-V) nodal reentrant tachycardia. Atrial premature stimuli at coupling intervals (S_1-S_2) of 340 and 270 ms further lengthen A-V nodal conduction (A-H) to 280 and 320 ms (**top** and **bottom,** respectively) and elicit sustained A-V nodal reentrant tachycardia.

coupling intervals (V_1-V_2) failed to elicit A-V nodal reentry.

One example is illustrated in Figure 2. The high right atrium was driven at a cycle length of 650 ms. The A_1-A_2, H_1-H_2 and A_1-A_2, A_2-H_2 curves were discontinuous because of a sudden increase in the A-V nodal conduction time (A_2-H_2) at an atrial premature coupling interval (A_1-A_2) of 450 ms. This reflects a failure of anterograde conduction over a fast A-V nodal pathway with resultant slow A-V nodal pathway conduction. The anterograde effective refractory periods of the fast and slow A-V nodal pathways were 450 and 270 ms, respectively. The critical A-V nodal conduction time (A_2-H_2) that induced an atrial echo phenomenon was 270 ms and the A-V nodal reentrant tachycardia zone coincided with the entire period of slow A-V nodal pathway conduction between atrial premature coupling intervals of 450 and 280 ms. The representative electrograms corresponding to Figure 2 are shown in Figures 3 and 4.

Observations after simultaneous A-V pacing: After the atrial and ventricular electrodes were connected to the new pacemaker (DDT), repeated programmed atrial or ventricular extrastimulation triggered simultaneous A-V stimulation at all premature coupling intervals (A_1-A_2 or V_1-V_2). The entire reciprocating tachycardia zone was completely abolished as a result of impulse collision in the A-V junction.

One example is shown in Figures 5 and 6. In Figure 5 (top), the V-A conduction pattern induced by programmed right ventricular extrastimulation was used as a reference. The right ventricle was driven at a cycle length (S_1-S_1) of 650 ms and a ventricular premature beat was delivered at a premature coupling interval (S_1-S_2) of 320 ms. The bipolar pacing spikes were relatively small and the atrial and ventricular electrograms were separate in the basic driving and prematurely stimulated beats. The prolongation of V-A conduction time after the ventricular premature stimulation (V_1-V_2 = 320 ms, A_1-A_2 = 380 ms) was consistent with retrograde conduction properties of the A-V node–His-Purkinje system.

After the atrial and ventricular electrodes were connected to the new pacemaker (DDT) (Fig. 5 [bottom] and 6), driving the right atrium or the right ventricle at a cycle length (S_1-S_1) of 650 ms resulted in simultaneous A-V stimulation. The pacing spikes generated by the new pacemaker had a greater amplitude compared with those produced by the close bipolar (1 cm apart) pacing in the right ventricle (Fig. 5, top). This difference was attributed to the longer electrode distance (approximately 12 cm) between the right atrium and the right ventricle. Simultaneous A-V stimulation resulted in the fusion of atrial and ventricular electrograms (Fig. 5 [bottom] and 6). Atrial or ventricular premature stimuli delivered at premature coupling intervals (S_1-S_2) of 450, 340 and 270 ms, respectively, also triggered simultaneous A-V stimulation without initiation of A-V nodal reentry. At these premature coupling intervals (S_1-S_2), atrial premature stimulation, when the electrodes were not connected to the new pacemaker, previously elicited paroxysms of sustained A-V nodal reentrant tachycardia (Fig. 3 [bottom] and 4). The new pacemaker (DDT) produced constant fusion of atrial and ventricular electrograms from simultaneous A-V stimulation; this suggested that collision of the impulse in the A-V junction had prevented establishment of an A-V nodal reentrant circuit.

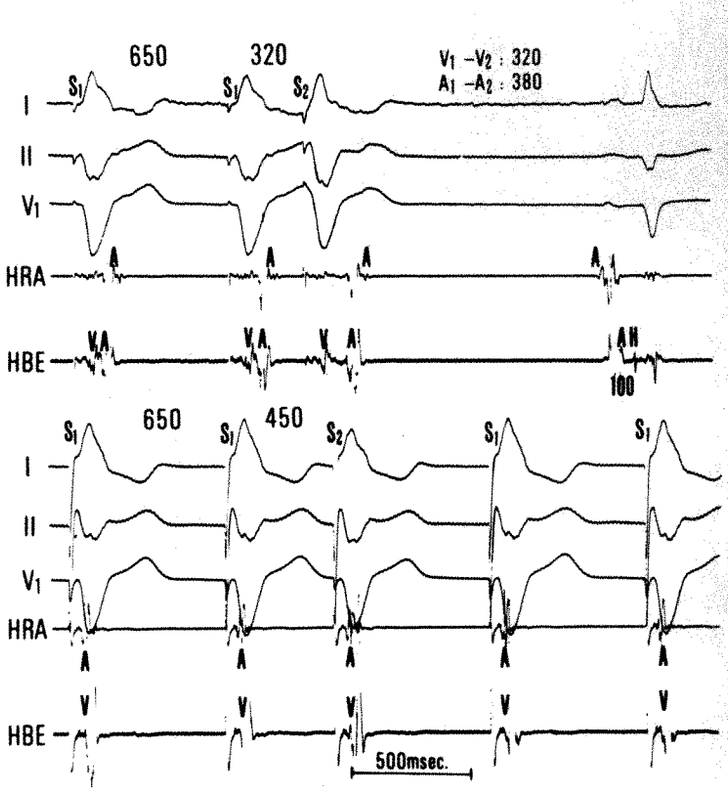

FIGURE 5. Same patient. **Top,** ventriculoatrial (V-A) conduction pattern generated by programmed ventricular extrastimulation prior to connection to the new pacemaker. The right ventricle is driven at a cycle length (S_1-S_1) of 650 ms. There is progressive prolongation of V-A conduction time as the ventricular premature coupling interval (S_1-S_2) gradually shortens, compatible with retrograde conduction by way of the A-V node–His-Purkinje system. At a premature coupling interval (S_1-S_2 or V_1-V_2) of 320 ms the corresponding A_1-A_2 interval is 380 ms. The atrial (A) and ventricular (V) electrograms are separated during both driving and premature beats. The pacing spikes are relatively small, reflecting close bipolar (1 cm apart) pacing in the right ventricle. **Bottom,** after connection of the atrial and ventricular electrodes to the new pacemaker (DDT), both the driving and premature stimuli (either from the atrium or from the ventricle) triggered simultaneous A-V stimulation, as evidenced by the occurrence of fusion between the atrial (A) and ventricular (V) electrograms. The atrial or ventricular driving cycle length (S_1-S_1) is 650 ms and the atrial or ventricular premature coupling interval (S_1-S_2) is 450 ms. No A-V nodal reentry could be elicited. The pacing spikes generated by the new pacemaker have greater amplitude compared with those produced by close bipolar right ventricular stimulation (**top**).

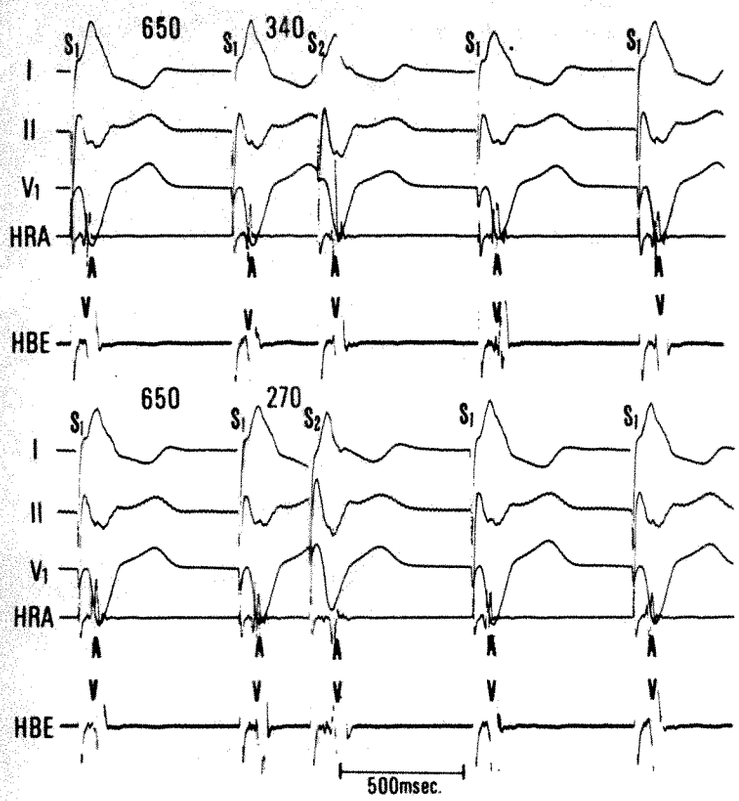

FIGURE 6. Same patient. After connection of the atrial and ventricular electrodes to the new pacemaker, atrial or ventricular premature beats at premature coupling intervals of 340 and 270 ms (**top** and **bottom**, respectively) triggered simultaneous A-V stimulation without initiation of A-V nodal reentry. Previously, atrial extrastimulation at these coupling intervals elicited paroxysms of A-V nodal reentrant tachycardia (Fig. 4).

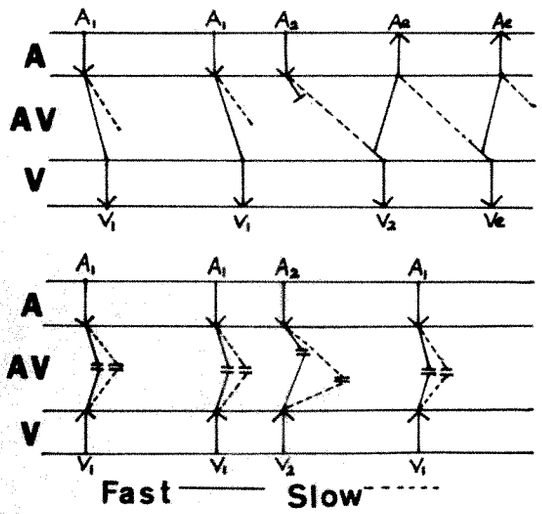

FIGURE 7. Diagrammatic representation of the new modality of cardiac pacing (DDT) in preventing initiation of atrioventricular (A-V) nodal reentrant tachycardia. **Top,** initiation of A-V nodal reentrant tachycardia by an atrial premature stimulus (A_2). **Bottom,** after connection to the new pacemaker, an atrial or ventricular signal triggers simultaneous A-V stimulation, resulting in simultaneous collision of anterograde and retrograde impulses in both fast and slow A-V nodal pathways. Consequently, no tachycardia can be elicited. A = atrium; AV = atrioventricular node; V = ventricle. A_1 and V_1 are atrial and ventricular responses corresponding to basic drives, respectively; A_2 and V_2 are atrial and ventricular responses corresponding to premature stimulation. Ae and Ve are atrial and ventricular responses during A-V nodal reentry.

Follow-up study: The course during the electrophysiologic study with the testing of the new pacemaker (DDT) was uneventful in each patient. Of the four patients, the condition of three (Cases 1 to 3) could be subsequently improved by therapy with a combination of digoxin, 0.25 mg/day, propranolol, 160 to 320 mg/day and quinidine gluconate, 1 to 1.8 g/day. Because of the presence of chronic obstructive lung disease and intolerance to quinidine, the remaining patient (Case 4) was treated with a combination of digoxin, 0.25 mg/day and verapamil hydrochloride, 320 mg/day. The results of medical therapy in all four patients appeared to be satisfactory in a follow-up period of 14 to 19 months.

Discussion

Principle and mode of action of simultaneous A-V pacemaker: Coumel et al.[10] first applied "simultaneous A-V stimulation" to suppress recurrence of supraventricular tachycardia. Spurrell and Sowton[11] subsequently developed a similar system of cardiac pacing—an atrial synchronous pacemaker with a 30 ms delay between atrial sensing and ventricular stimulation. They were able to demonstrate a significant narrowing of the reentrant supraventricular tachycardia zone, thus providing a new electrophysiologic principle of cardiac stimulation aimed primarily at prevention of the occurrence of paroxysmal tachycardia.

It is well recognized that either an atrial or a ventricular premature stimulus can induce a paroxysm of

supraventricular tachycardia.[8,12,13] The experimental pacemaker described in our study, in contrast to those of Coumel et al.[10] and Spurrell and Sowton,[11] is capable of sensing either an atrial or a ventricular signal and, in turn, triggers "simultaneous A-V stimulation." Complete abolition of the tachycardia zone is possible, as seen in our four patients with A-V nodal reentrant tachycardia, using a slow A-V nodal pathway for anterograde conduction and a fast A-V nodal pathway for retrograde conduction. The occurrence of sustained A-V nodal reentrant tachycardia is dependent on adequate anterograde slow A-V nodal pathway conduction and on adequate retrograde fast A-V nodal pathway conduction as well.[14] Simultaneous A-V stimulation triggered by an atrial or a ventricular premature beat presumably creates simultaneous collision of anterograde and retrograde impulses in both fast and slow A-V nodal pathways, thereby preventing establishment of the A-V nodal reentrant tachycardia circuit (Fig. 7).

Problems in clinical applications: These preliminary results suggest that implantable pacemakers with this new modality of cardiac pacing may soon be a reality. Nevertheless, several factors should be considered prior to its clinical use. First, medical therapy remains the treatment of choice in patients with recurrent supraventricular tachycardia. Various combinations of two or more medications (digitalis, quinidine, disopyramide and procainamide) should be tried if a single medication fails to control or prevent the tachycardia. Medications, such as verapamil,[15] currently under investigation in the United States may be of clinical use in the future. Second, an electrophysiologic study is required to test the efficacy of the new pacemaker (DDT) before its permanent implantation in each patient. Theoretically, the presence of functional discordance between anterograde and retrograde properties of the A-V conduction system may limit the effectiveness of this new pacemaker in abolishing the tachycardia zone. Therefore, in certain instances, it is expected that this new pacema of narrowing the tachycardia z to that observed by Spurrell a atrial synchronized type of c study is needed to determine pacemaker in preventing othe ular tachycardia. Third, as is atrial synchronous pacing, tho sary in order to assure adeq sensing in some patients.

Fourth, it is not advisable t of pacemaker in patients prone or ventricular tachyarrhyth tachycardia, atrial flutter-fi tachycardia and ventricular fib atrial or ventricular arrhythm pacemaker, initiating rapid sti lation. The new pacemaker (DI a built-in refractory period of maximal pacing rate to 231/n Spurrell and Sowton,[11] the buil this type of pacemaker should b its maximal rate to 200/min. implantation of such a pacem avoided in patients with a kno opment of atrial or ventricu Concomitant administration o may therefore remain necessa Lastly, like any form of ventricu A-V stimulation results in the l to ventricular filling. Patients w with or without congestive h regurgitation should be carefu ceiving this new mode of cardi

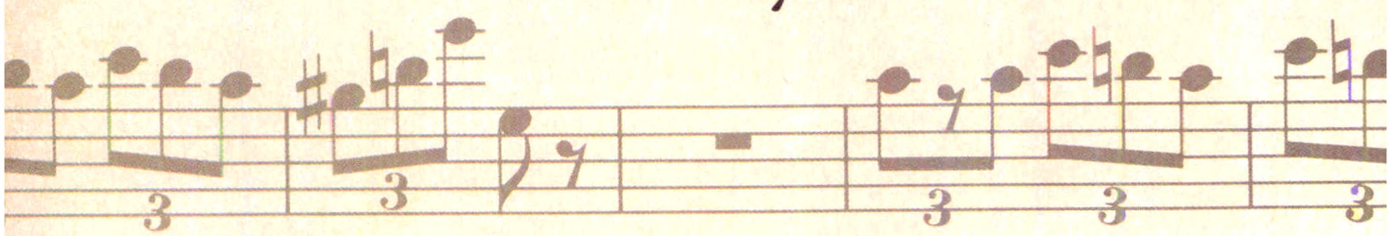
Introducing The Varian V-3400

For the next step after a diuretic...

New thinking in tune with today's antihypertensive life-style



Hemodynamic harmony

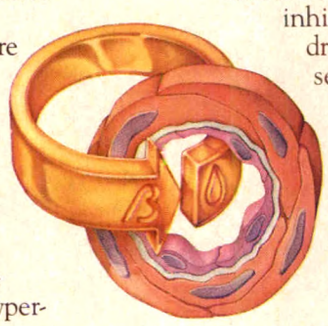
With today's medical emphasis on full control of hypertension, the need is for therapy that will not create new problems for your patients in place of the ones it solves.

Accordingly, more and more physicians are discovering the logic of combining a diuretic, Apresoline, and a beta blocker.[1-8]

Unlike beta blockers, Apresoline, an oral vasodilator, acts directly to reduce the high peripheral resistance that is "the hemodynamic hallmark of all hypertensive diseases...."[2]

Unlike Apresoline, beta blockers specifically reduce cardiac output, which tends to rise by reflex action with vasodilation.[1-8]

Thus, together, both agents tend to support each other's strengths and minimize weaknesses.



Fewer discordant side effects

Apresoline, an oral antihypertensive agent whose only action is direct arteriolar dilation, avoids many of the problems associated with some adrenergic inhibitors. Sexual dysfunction, drowsiness, lethargy, and sedation are virtually unknown. Postural hypotension is rare. As with any antihypertensive agent, use with caution in patients with advanced renal damage. Contraindicated in coronary artery disease.

Logical complements to a diuretic...

Apresoline® & (hydralazine)

the beta blockers

Apresoline® hydrochloride
(hydralazine hydrochloride USP)

TABLETS

INDICATIONS

Essential hypertension, alone or as an adjunct.

CONTRAINDICATIONS

Hypersensitivity to hydralazine; coronary artery disease; and mitral valvular rheumatic heart disease.

WARNINGS

Hydralazine may produce in a few patients a clinical picture simulating systemic lupus erythematosus. In such patients hydralazine should be discontinued unless the benefit-to-risk determination requires continued antihypertensive therapy with this drug. Symptoms and signs usually regress when the drug is discontinued but residua have been detected many years later. Long-term treatment with steroids may be necessary.

Complete blood counts, L.E. cell preparations, and antinuclear antibody titer determinations are indicated before and periodically during prolonged therapy with hydralazine even though the patient is asymptomatic. These studies are also indicated if the patient develops arthralgia, fever, chest pain, continued malaise or other unexplained signs or symptoms.

A positive antinuclear antibody titer and/or positive L.E. cell reaction requires that the physician carefully weigh the implications of the test results against the benefits to be derived from antihypertensive therapy with hydralazine.

Use MAO inhibitors with caution in patients receiving hydralazine.

When other potent parenteral antihypertensive drugs, such as diazoxide, are used in combination with hydralazine, patients should be continuously observed for several hours for any excessive fall in blood pressure. Profound hypotensive episodes may occur when diazoxide injection and Apresoline (hydralazine hydrochloride) are used concomitantly.

Usage in Pregnancy

Animal studies indicate that hydralazine is teratogenic in mice, possibly in rabbits, and not in rats. Teratogenic effects observed were cleft palate and malformations of facial and cranial bones. Although clinical experience does not include any positive evidence of adverse effects on the human fetus, hydralazine should not be used during pregnancy unless the expected benefit clearly justifies the potential risk to the fetus.

PRECAUTIONS

Myocardial stimulation produced by Apresoline can cause anginal attacks and ECG changes of myocardial ischemia. The drug has been implicated in the production of myocardial infarction. It must, therefore, be used with caution in patients with suspected coronary artery disease.

The "hyperdynamic" circulation caused by Apresoline may accentuate specific cardiovascular inadequacies. An example is that Apresoline may increase pulmonary artery pressure in patients with mitral valvular disease. The drug may reduce the pressor responses to epinephrine. Postural hypotension may result from Apresoline, but is less common than with ganglionic blocking agents. Use with caution in patients with cerebral vascular accidents.

In hypertensive patients with normal kidneys who are treated with Apresoline, there is evidence of increased renal blood flow and a maintenance of glomerular filtration rate. In some instances improved renal function has been noted where control values were below normal prior to Apresoline administration. However, as with any antihypertensive agent, Apresoline should be used with caution in patients with advanced renal damage.

Peripheral neuritis, evidenced by paresthesias, numbness, and tingling, has been observed. Published evidence suggests an antipyridoxine effect and the addition of pyridoxine to the regimen if symptoms develop.

Blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura, have been reported. If such abnormalities develop, discontinue therapy.

Periodic blood counts are advised during prolonged therapy.

The Apresoline tablets (10 and 100 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Adverse reactions with Apresoline are usually reversible when dosage is reduced. However, in some cases it may be necessary to discontinue the drug.

Common: Headache; palpitations; anorexia; nausea; vomiting; diarrhea; tachycardia; angina pectoris.

Less frequent: Nasal congestion; flushing; lacrimation; conjunctivitis; peripheral neuritis, evidenced by paresthesias, numbness, and tingling; edema; dizziness; tremors; muscle cramps; psychotic reactions characterized by depression, disorientation, or anxiety; hypersensitivity (including rash, urticaria, pruritus, fever, chills, arthralgia, eosinophilia, and, rarely, hepatitis); constipation; difficulty in micturition; dyspnea; paralytic ileus; lymphadenopathy; splenomegaly; blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura; hypotension; paradoxical pressor response.

DOSAGE AND ADMINISTRATION

Initiate therapy in gradually increasing dosages; adjust according to individual response. Start with 10 mg 4 times daily for the first 2 to 4 days, increase to 25 mg 4 times daily for balance of first week. For second and subsequent weeks, increase dosage to 50 mg 4 times daily. For maintenance, adjust dosage to lowest effective levels.

The incidence of toxic reactions, particularly the L.E. cell syndrome, is high in the group of patients receiving large doses of Apresoline.

In a few resistant patients, up to 300 mg Apresoline daily may be required for a significant antihypertensive effect. In such cases, a lower dosage of Apresoline combined with a thiazide, reserpine, or both may be considered. However, when combining therapy, individual titration is essential to insure the lowest possible therapeutic dose of each drug.

HOW SUPPLIED

Tablets, 10 mg (pale yellow, dry-coated); bottles of 100 and 1000.

Tablets, 25 mg (deep blue, dry-coated) and 50 mg (light blue, dry-coated); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.

Tablets, 100 mg (peach, dry-coated); bottles of 100.

Dispense in tight, light-resistant container (USP).

Why your hospital needs a defibrillator on every floor.

All hospital elevators are notoriously slow. And with good reason, because in a hospital, the elevators are really freight elevators to move people and patients, equipment and supplies.

But when a life is ticking away, you can't afford to be waiting for the elevator. Will it come straight down? Or will it stop on another floor to pick up a patient on a gurney or to move on a food cart or to pick up linen or to transport visitors? Who knows? All you *really* know is that a life is ticking away and you're waiting for the elevator.

Considering what's at stake, and considering the relatively low cost of defibrillators, your hospital can't possibly make a wiser investment than installing an emergency cart on every floor. A *Physio-Control* emergency cart. *Topped* by a Physio-Control Lifepak 6 defibrillator/monitor. *Then* you're protected. And so are your people. And so are your patients.

The time to do it is *now.*

Only Physio-Control makes the Lifepak.®

Lifepak and Physio-Control are registered trademarks of Physio-Control Corporation. World leader in acute cardiac care systems.

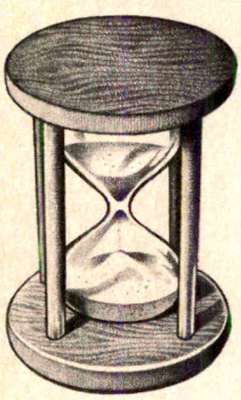
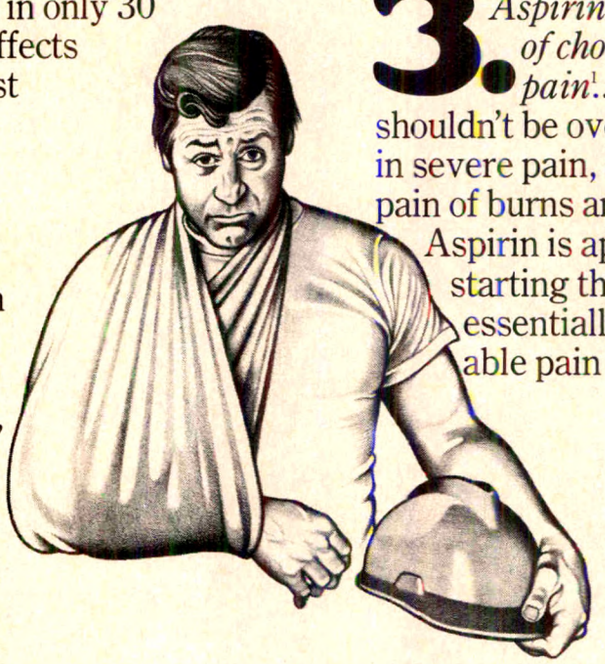
10 reasons why medicine's most analgesic

1. *Aspirin is the prototype among analgesics/antipyretics.*[1] It continues as the standard for non-narcotic analgesic efficacy[2]...effective against most types of pain.



2. *Aspirin acts quickly and predictably.* Following ingestion, appreciable plasma levels are reached in only 30 minutes or less.[2] Effects of a single dose last 4-6 hours.[3]

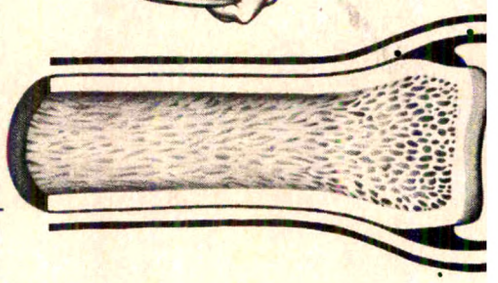
3. *Aspirin is the drug of choice for mild pain*[1]...but its use shouldn't be overlooked in severe pain, such as the pain of burns and trauma.[4] Aspirin is appropriate starting therapy for essentially all treatable pain problems.[5]

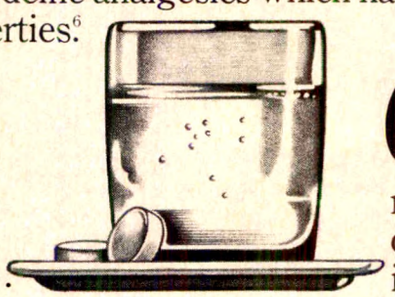


4. *Aspirin is preferable to narcotics* when practical, since much pain is chronic and recurring.[4] However, even when narcotics are required, concomitant use of aspirin may permit smaller-than-usual doses of the potentially dependence-producing agent.[4]

BAYER + CODEINE

5. *Aspirin is basic anti-inflammatory therapy.* This action makes it much more useful for inflammatory conditions, such as rheumatoid arthritis, than acetaminophen, propoxyphene or codeine analgesics which have no anti-inflammatory properties.[6]



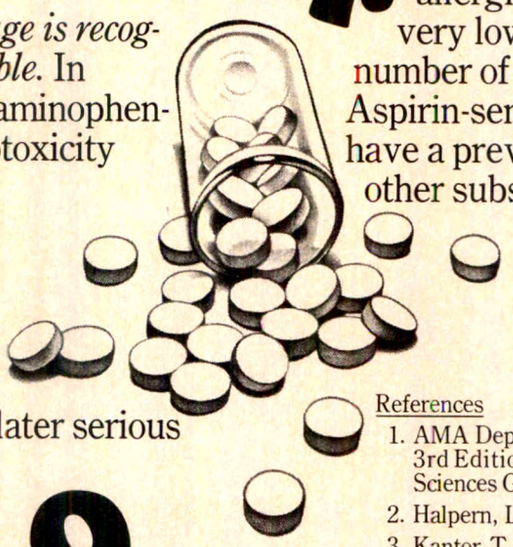


6. *Aspirin has a highly favorable benefit-to-risk ratio.* Aspirin ranks as one of medicine's best-tolerated drugs.[5,7] Serious adverse reactions are infrequent with usual analgesic doses.[1]

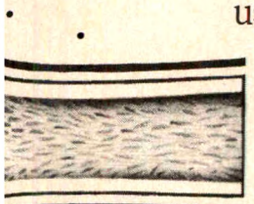
aspirin is still widely used

7. *Aspirin has a low potential for allergic reactions.* The incidence of allergic reactions to aspirin is very low considering the vast number of tablets taken each year.[8] Aspirin-sensitive patients will usually have a previous history of allergy to other substances.[9]

8. *Aspirin overdosage is recognizable, treatable.* In contrast, acetaminophen-induced hepatotoxicity that may result from overdosage is much less amenable to therapy...and variable early symptoms may not be accurately predictive of later serious complications.[10]



9. *Aspirin is inexpensive.* Aspirin still costs patients only about a penny per tablet. It is less expensive than most commonly used drugs for pain and a great deal less expensive than the newer non-steroidal antiarthritic agents.



10. *Aspirin is unique.* No analgesic, no antipyretic, no anti-inflammatory agent can match its broad clinical versatility, its almost 80 years of experience or its outstanding record of therapeutic effectiveness.

Spectrax-SX shown approximately actual size

Medtronic leads the way to man's heart with new versatility for treating a broad spectrum of conditions.

Spectrax™-SX ...the remarkable new ultra-programmable pacemaker from Medtronic ...allows creation and adaptation of a set of pacing parameters ideal for each individual patient, today and for years to come. It combines lithium longevity with unexcelled adjustability in the smallest programmable available.

The Spectrax-SX pacemaker lets you prescribe treatment parameters for each particular patient at implant, then respond non-invasively with exceptional accuracy to changes in condition, anticipated or unanticipated. Adjust rate, pulse width, sensitivity, refractory period, hysteresis, pulse amplitude and pacing mode. The Spectrax-SX system even gives you an exact readout on pacemaker performance.

The Spectrax-SX pacemaker provides for precise management of a wide variety of previously uncontrollable conditions. Its extensive versatility can make possible a more comfortable, normally active life for many patients.

SPECTRAX™

...broadening the spectrum of precise patient management

Medtronic®

...leading the way to man's heart.

MEDTRONIC PRODUCT INFORMATION SUMMARY

Medtronic® Implantable Pulse Generators

Intended Uses—Ventricular pacing using an implantable ventricular pulse generator and lead system are for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses). An atrial pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation disorders but with intact, functioning A-V conduction systems.

Contraindications—There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate in patients with normal conduction systems. In certain patients with anomalies of the conduction system (WPW syndrome and related conditions), patients may be benefited or harmed by cardiac pacing. Therefore, electrophysiologic studies are required prior to therapeutic application of pacing. In addition, the patient's age and medical condition may dictate the particular pacing system and implantation procedure used by the physician.

Warnings—Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of unipolar pulse generators or bipolar pulse generators implanted in the unipolar mode because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. (See product labeling for a complete list of warnings and precautions.)

Precautions—The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects—Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

Model 9700/9701 Programmers

Intended Use—The Medtronic® Model 9700 and 9701 Programmers are designed to be used by a physician for noninvasively programming the Medtronic® pulse generators listed in their respective technical manuals. The programmers may also be used to measure the rate and pulse width of implanted pacemakers.

There are no known contraindications or major potential complications associated with use of the programmer. However, these devices should not be used without prior study of the technical manual supplied with each programmer.

Warnings—The programmers should only be used for programming the Medtronic® pulse generators designated in the respective technical manuals. Direct stimulation by energy coupling may occur if the programmers are used on other implanted devices. The programmers are not compatible with pulse generators of other manufacturers. See product labeling for a complete list of warnings and precautions.

AJC-1/80

In cardio-diagnostic procedure, detail is everything, and the key to detail in ultrasound scanners, is resolution. The finer the resolution, the clearer the detail, and the easier it is to make an accurate diagnosis of a cardiac condition.

Our new heart dedicated Sonolayergraph SSH-10A is unsurpassed when it comes to resolution, providing an ultrafine diagnostic image.

The SSH-10A Sonolayergraph represents the state-of-the-art in highly advanced high speed ultrasonic electronic scanners. A real time cross sectional, two-dimensional "B" mode image of the heart structure can be clearly obtained by positioning the probe on the chest wall. Valve movements, chamber size and detail of the internal structures of the heart can be clearly observed, measured and diagnosed. The SSH-10A is also capable of obtaining two "M" mode tracings simultaneously as well as Kymograph* studies. With its 78° true wide angle sector range, the SSH-10A provides a permanent EKG, phono-cardiogram, and patient ID with digital caliper read-out on the CRT in the "B" mode. The two angles of the "M" mode can also be easily displayed independently on a second CRT and/or strip recorder. Additionally, the "M" mode provides four channels of physiological monitoring, EKG, phono-cardiogram, carotid pulse and apex pulse.

When it comes to providing an accurate picture of your patient's heart condition, there are two things to remember, resolution and Toshiba.

*Kymograph is a composite of "B" mode images obtained from a gated EKG.

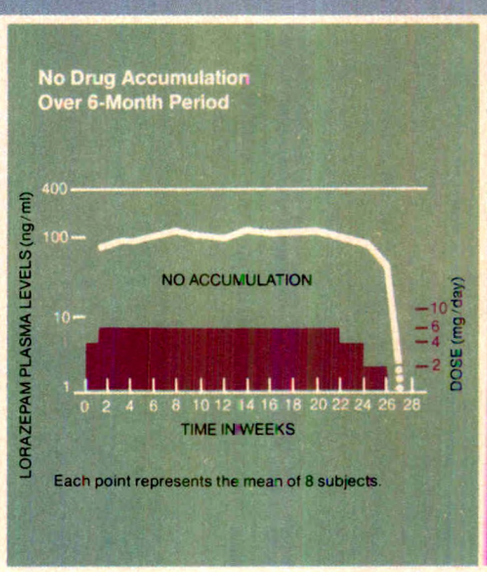
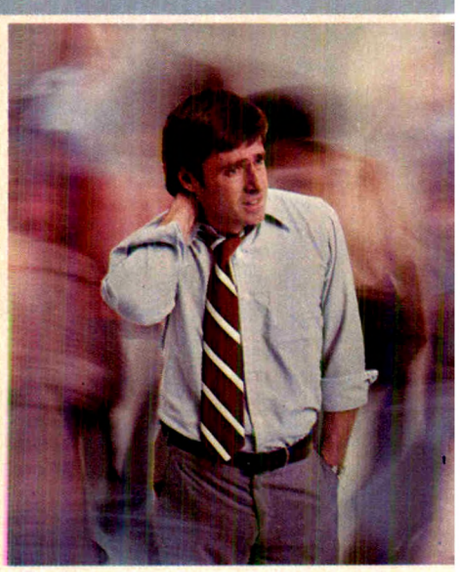
How do you choose a minor tranquilizer?





Wyeth Laboratories
Philadelphia, PA 19101
™

Pharmacokinetics

Ativan (lorazepam) is eliminated more rapidly than other benzodiazepines; generates no clinically active metabolites. The half-life of free lorazepam is about 12 hours; steady-state blood levels are attained in 2-3 days. (Comparable data for diazepam: 20-50 hours and at least 7-10 days.) Ativan shows no evidence of accumulation, even when given in high doses for as long as 6 months. (The pharmacokinetic profile of a drug can define such characteristics as absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Anxiety neuroses

In many nationwide studies involving thousands of patients with anxiety neuroses, Ativan (lorazepam) consistently provided significant relief of anxiety, tension, agitation and irritability as measured by standard Hamilton, Global (physician rated) and 35-Item (patient self-rated) scales.

Copyright © 1979, Wyeth Laboratories Div. of AHPC, N.Y., N.Y. All rights reserved.

They're all about the same, aren't they? Until recently, that seemed to sum up the prevalent attitude about the benzodiazepines. After all, they all work similarly and all are effective anxiolytics. With seven of these compounds now available, however, differences have begun to emerge. Foremost among them: different metabolic pathways, which distinguish the relatively short-acting Ativan (lorazepam) from long-acting diazepam, clorazepate and chlordiazepoxide. At the same time, your choice can be made with confidence in the clinical record of Ativan, which confirms its value in anxiety neuroses and in significant anxiety associated with functional or organic disorders, as well as in older patients.

Consider the record of Ativan:

Anxiety in cardiovascular disorders

Ativan (lorazepam) has been specifically evaluated and found effective in seven common protocol, double-blind studies involving 423 patients (211 on Ativan) whose anxiety was related to organic and functional cardiovascular disorders. The cardiovascular component has not, of course, been shown to be significantly benefited by such therapy.

Anxiety in gastrointestinal disorders

So far, nine common protocol, double-blind studies of Ativan have focused on anxious patients with functional or organic gastrointestinal complaints (457 patients, 234 on Ativan). Ativan was clearly effective in reducing the anxiety of these patients. The gastrointestinal component has not, of course, been shown to be significantly benefited by such therapy.

Anxiety in the aging patient

Because its simple metabolism is not readily impaired with advancing age, and accumulation is not likely to present a problem, Ativan is a good choice for older patients. Those who have trouble swallowing solid medication appreciate the small Ativan tablet, which is tasteless and disintegrates within seconds in water or fruit juice.

Ativan® IV for (lorazepam) Anxiety

See important information on following page.

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability and insomnia associated with anxiety neuroses and transient situational disturbances; anxiety associated with depressive symptoms and as a treatment of symptoms of anxiety if such symptoms are a significant feature of functional or organic disorders, particularly gastrointestinal or cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatric patients requires caution and frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring of vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for (lorazepam) Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

Comparison of M Mode Echocardiography and Pathologic Findings in the Hypoplastic Left Heart Syndrome

JOHN L. BASS, MD
GIORA BEN-SHACHAR, MD
JESSE E. EDWARDS, MD, FACC

Minneapolis, Minnesota

The M mode echocardiograms and pathologic specimens from 18 infants with the hypoplastic left heart syndrome were compared to determine the accuracy with which the echocardiogram reflects the state of the mitral valve, left ventricle and aortic valve, and its limitations in establishing this diagnosis. Mitral valve echoes were recorded in 7 of the 11 cases with an anatomic mitral valve orifice diameter greater than 3 mm. Ventricular septal echoes were found only in the seven cases in which the mitral valve was recorded. Differences between echocardiographic and anatomic left ventricular internal dimensions were not statistically significant in this small group. When aortic valve echoes were recorded, this valve was always patent in the anatomic specimen. The aortic valve was atretic in 9 of the 11 cases in which no aortic valve echoes were present. The echocardiographic and anatomic aortic root dimensions had a statistically significant correlation ($p < 0.05$), but there was considerable scatter in the data.

None of the 18 infants met all of the previously proposed criteria for the echocardiographic diagnosis of hypoplastic left heart syndrome. An echocardiographic left ventricular dimension of 10 mm or greater was present in five cases (28 percent), and an aortic root dimension of 10 mm or greater in six (33 percent). The most reliable echocardiographic finding was excursion of 5 mm or less of the anterior leaflet of the mitral valve or inability to detect the mitral valve. Noninvasive findings are not always sufficient to establish the diagnosis of hypoplastic left heart syndrome, and further studies may be necessary in some patients.

The hypoplastic left heart syndrome involves a spectrum of hypoplasia or atresia of the mitral valve, left ventricle and aortic valve. Infants with this syndrome usually have congestive heart failure within the 1st few days of life. Efforts at surgical palliation have been largely unsuccessful, and the majority of the affected infants die before 1 month of age.[1] The outlook for infants with a diagnosis of hypoplastic left heart syndrome may affect therapeutic decisions. For this reason it is important to distinguish infants with this syndrome from infants with a similar clinical presentation whose condition might respond to medical management (sepsis or persistent fetal circulation) or might benefit from surgical intervention (critical aortic stenosis or obstructed total anomalous pulmonary venous drainage).

Echocardiographic findings characteristic of hypoplastic left heart syndrome have been described,[2–7] and echocardiography has greatly aided evaluation of infants suspected of having this syndrome. A recent report[8] has cautioned against relying on echocardiography alone to establish the diagnosis when findings are not typical. In some centers, additional diagnostic studies are performed only if echocardiographic findings are not classic.[4,9,10] It is therefore important to determine the accuracy of the echocardiogram in reflecting the actual anatomic findings

During diastole, echoes of the mitral valve posterior leaflet move away from echoes of the anterior leaflet. **b,** specimen of left atrium (LA), hypoplastic left ventricle (LV) and hypoplastic mitral valve; the anterior leaflet (AM) of the mitral valve is more apparent than the posterior leaflet in this perspective.

in hypoplastic left heart syndrome and its limitations in establishing the diagnosis.

Previous studies[2–7] have primarily described echocardiographic findings in infants with hypoplastic left heart syndrome and have not correlated these findings with the anatomic features. We compared echocardiographic and pathologic findings in 18 infants with hypoplastic left heart syndrome in order to evaluate the limitations of echocardiography in establishing the diagnosis as well as the reliability with which it reflects the state of the mitral and aortic valves and the left ventricle.

Methods

At the University of Minnesota Hospitals between 1974 and 1978, heart specimens were obtained at autopsy from 18 infants with anatomically established hypoplastic left heart syndrome who had undergone M mode echocardiography during life.

Autopsy specimens: In the pathologic specimens, each of which had been fixed in an undistended state in formaldehyde, the diameters of the mitral and aortic valves, when present, were determined by finding the largest probe diameter that would easily pass through the valve orifice. When there was critical aortic stenosis or aortic valve atresia, the diameter of the aortic root was measured. An index of the diameter of the left ventricle was determined by measuring the horizontal distance from the center of the base of the posterior mitral valve leaflet to the center of the base of the right aortic cusp. This dimension was chosen because of its similarity to the location used in echocardiographic determination of the internal dimension of the left ventricle.

Echocardiographic measurements: The M mode echocardiograms had been recorded with a Smith-Kline Instruments Ekoline® ultrasonoscope using a 3.5 or 5.0 megahertz

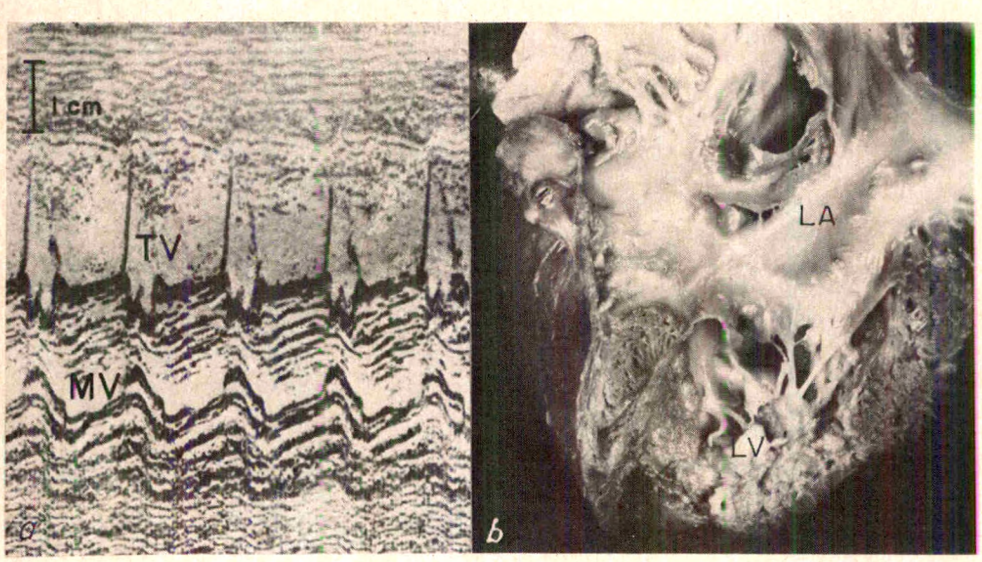

FIGURE 2. Case 1. Parachute mitral valve associated with hypoplastic left ventricle and other anomalies. **a,** echocardiogram. Mitral (MV) and tricuspid valve (TV) echoes are recorded simultaneously. During diastole, echoes of the posterior mitral leaflet exhibit paradoxic anterior motion, in parallel with those of the anterior leaflet. **b,** specimen of left atrium (LA), mitral valve and left ventricle (LV). Within the latter is a solitary papillary muscle characteristic of parachute mitral valve. An associated ventricular septal defect is seen in the background.

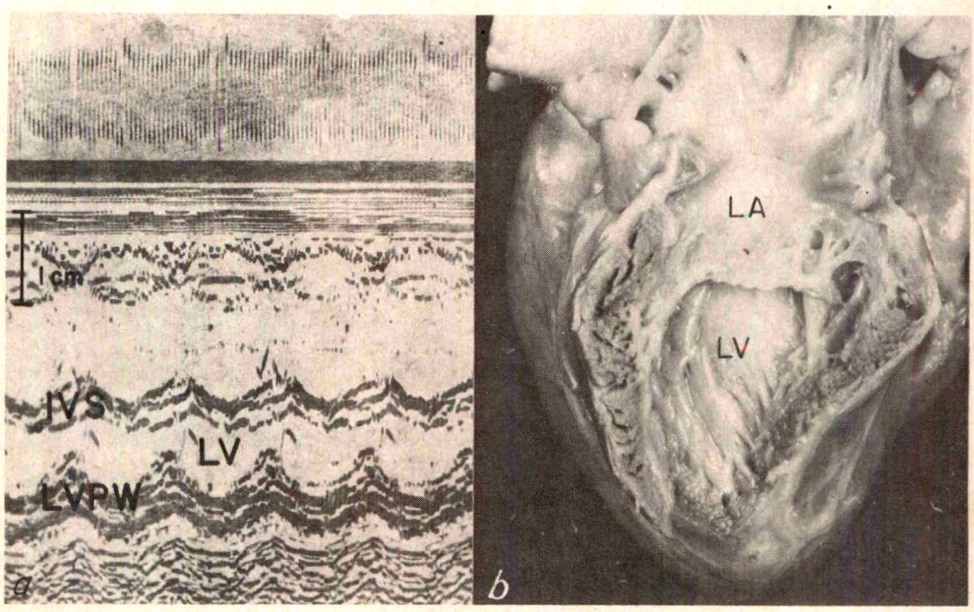

FIGURE 3. Case 6. Aortic atresia with ventricular septal defect and parachute mitral valve deformity. **a,** echocardiogram. A small left ventricular cavity (LV) is recorded in which mitral valve echoes can be seen during early diastole. The motion of the intraventricular septal (IVS) echoes is paradoxic. LVPW = posterior wall of left ventricle. **b,** specimen showing the left atrium (LA), mitral valve and left ventricle (LV). The latter is moderately hypoplastic. An associated ventricular septal defect is out of view in this perspective.

transducer. Fourteen of the echocardiographic studies were performed by an experienced echocardiographer; an additional four studies were performed at night by the pediatric cardiology fellow on call, usually without supervision by an experienced echocardiographer.

Mitral valve excursion in the echocardiogram was measured as the vertical distance from the D point to the E point of mitral valve echoes. Patterns of motion of the echoes of the anterior and posterior mitral valve leaflets were also noted (Fig. 1 and 2). The left ventricular end-diastolic diameter was measured between the endocardial echoes of the ventricular septum and the left ventricular posterior wall at the time of the peak of the R wave of the electrocardiogram. Ventricular septal motion was noted and described as normal or paradoxic (Fig. 3). The diameter of the aortic root was measured at the time of the peak of the R wave of the electrocardiogram when parallel motion of the aortic walls was demonstrated in the echocardiogram. Frequently, echoes from the aortic cusps were not identifiable; in these cases, the measured diameter of the aortic root may have been tangential and thus, may not represent a true diameter. Aortic valve cusps were said to be recorded when opening or closing echoes were noted (Fig. 4) but not when linear echoes were recorded within the aortic root (Fig. 5).

Evaluation of findings: Although the echocardiograms and pathologic specimens were examined with knowledge that the hypoplastic left heart syndrome was present, the exact anatomic details were not known. The results were examined to determine the frequency with which the echocardiograms correctly predicted the state of the aortic valve, mitral valve and left ventricle in each heart. When those structures had been recorded, the anatomic and echocardiographic mea-

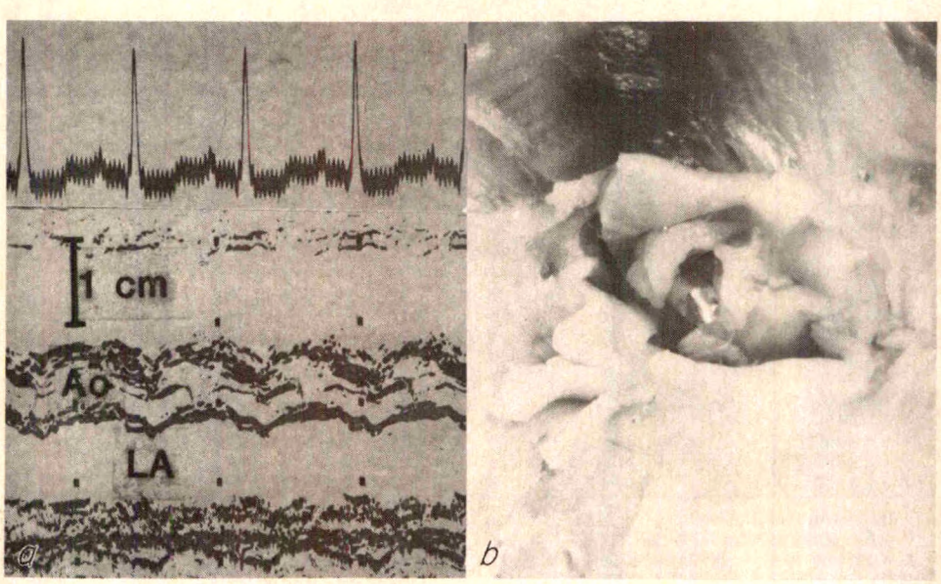

FIGURE 4. Case 5. Aortic valve stenosis with a hypoplastic left ventricle and parachute mitral valve deformity. **a,** echocardiogram. The aortic (Ao) root is recorded with echoes of opening and closure of the aortic valve, suggesting that the aortic valve is patent. LA = left atrial cavity. **b,** specimen of the stenotic aortic valve viewed from above.

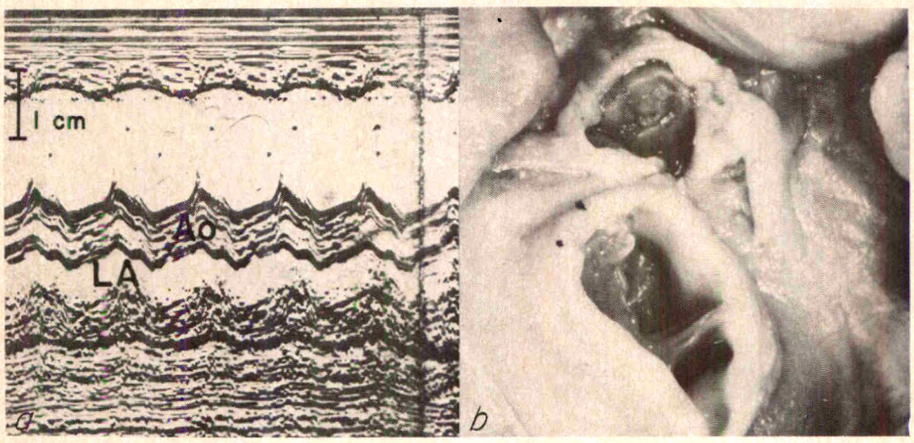

FIGURE 5. Case 6. Aortic atresia with ventricular septal defect and parachute mitral valve deformity. **a,** echocardiogram. Multiple linear echoes are recorded within the aortic (Ao) root. No echoes suggesting opening or closure of the aortic valve are present. In most, but not all cases, this pattern corresponded with aortic atresia. LA = left atrial cavity. **b,** transected pulmonary trunk (**below**) and ascending aorta (**above**) showing corresponding valve. The aorta is hypoplastic and its valve is atretic.

surements were statistically compared. In addition, we compared our findings with published criteria[11] for the echocardiographic diagnosis of hypoplastic left heart syndrome to determine how many of our cases might have been correctly diagnosed with echocardiography.

Results

Of the 18 infants, 13 were male and 5 were female (male to female ratio 2.6:1). The average ages at presentation and at death (excluding one patient who presented at age 6 weeks) were 2.9 days and 4.4 days, respectively. The echocardiographic and anatomic findings are summarized in Table I.

Pathologic findings: In every case, the pathologic examination revealed a smaller than anticipated left ventricular diameter as determined qualitatively. Associated valve changes were as follows: (1) coexistent aortic and mitral atresia (three cases); (2) aortic atresia with hypoplastic mitral valve (six cases); (3) mitral atresia with patent aortic valve (two cases, one with double outlet right ventricle); and (4) hypoplastic mitral valve and patent aortic valve (seven cases, one with an endocardial cushion defect involving the atrioventricular [A-V] valves).

Mitral valve: The mitral valve was atretic in 5 and hypoplastic in 12 of the 18 specimens; in 1 heart, the mitral valve mechanism was part of a partial type of common A-V canal (cleft anterior mitral leaflet with intact tricuspid valve). The echocardiogram had not demonstrated mitral valve echoes in any of the five cases with mitral atresia.

In 7 of the 13 hearts with pathologic confirmation of a hypoplastic mitral valve, the echocardiogram had shown mitral valve echoes. The mitral valve orifice ranged in diameter from 4 to 7 mm, in six of the seven hearts. The specimen with the partial type of common

A = atretic; AVC = atrioventricular canal defect; CE = could not evaluate; Echo = echocardiographic; NI = normal; NR = not recorded; P = parallel; PA = type A paradoxic ventricular septal motion; PB = type B paradoxic ventricular septal motion; S = stenotic.

A-V canal had a mitral valve orifice diameter of 10 mm; the echocardiogram had shown a mitral excursion of 8 mm. In the remaining 6 of the 13 cases with hypoplastic mitral valve, no mitral echoes were recorded. In two of these, the mitral orifice was about 1 mm in diameter and in the others, 3 to 5 mm. The condition of one specimen was inappropriate for measurement of orifice diameter. The anatomic diameters of the mitral valve orifice had a statistically significant correlation with echocardiographically recorded excursions of the mitral valve ($r = 0.73$, $p < 0.05$) (Fig. 6).

There were three examples of parachute mitral valve. The echocardiographic findings were not uniform in these cases. One of these hearts was among the two with paradoxic motion of the mitral leaflet; the other two hearts with parachute mitral valve did not display paradoxic motion.

Left ventricle: In three cases, each with coexistent aortic and mitral atresia, the left ventricular chamber was represented by an endocardium-lined slit in the pathologic specimen. Four other specimens had a very small left ventricular chamber (diameter 2 to 5 mm). The remaining 11 specimens had lesser degrees of hypoplasia with a left ventricular diameter of 8 to 12 mm. The echocardiogram had not recorded the left ventricle in any of the seven cases with a left ventricular diameter of 5 mm or less. In one of these seven cases, echoes that had been interpreted as originating from the ventricular septum at the time of the initial examination were actually reflected from the tricuspid valve and its supporting apparatus (Fig. 7). In 7 of the 11 cases with a larger left ventricle (diameter 8 mm or greater), this chamber was identified on echocardiographic study. All seven echocardiograms had been performed by an experienced echocardiographer. Ventricular septal motion was paradoxic in the echocardiogram of six of these seven cases. In the remaining four cases with a similar ventricular diameter, the left ventricle was not recorded in the echocardiogram. The correlation between pathologic and echocardiographic diameters of the left ventricle was not statistically significant ($r = 0.63$, $p > 0.05$) (Fig. 8).

Aortic valve: The aortic valve was atretic in 9 of the 18 specimens, stenotic in 7 and normal in 2. No aortic valve echoes were recorded in the nine cases with aortic valve atresia. Echoes from the opening of the aortic valve were present in five of the seven cases with aortic stenosis. In the remaining two cases, the aortic valve was normal on both echocardiographic and pathologic study.

The internal diameter of the aortic root measured 1 to 7 mm in the 18 pathologic specimens. Echocardiographically, the aortic root was not recorded in three specimens, each with an internal aortic root diameter of 3 mm or less. The aortic root was recorded in the other 15 specimens; these had an echocardiographic external aortic root diameter of 5 to 14 mm and an anatomic internal diameter of 2 to 7 mm. The anatomic and echocardiographic aortic root diameters had a statistically significant correlation ($r = 0.50$, $p < 0.05$), but there was considerable scatter (Fig. 9).

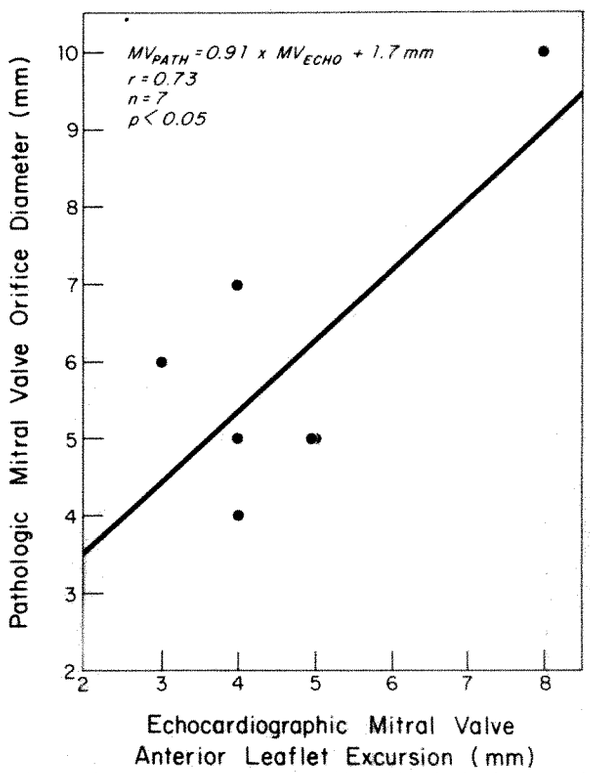

FIGURE 6. Comparison of the echocardiographic mitral valve excursion (MV_{ECHO}) and the anatomic diameter of the mitral valve orifice (MV_{PATH}). Although the correlation is statistically significant, the clustering of cases at both ends of the regression line makes it hazardous to predict the anatomic mitral orifice from the echocardiogram on the basis of these data.

Comment

Several investigators[2–7] have reported M mode echocardiographic findings in patients with the hypoplastic left heart syndrome. The majority of these studies[2–6] have compared these findings with those of normal infants in order to establish criteria for the echocardiographic diagnosis of this syndrome. Farooki et al.,[7] in 1976, noted a "gross correlation" between the aortic root diameter measured angiographically or pathologically and that measured echocardiographically. Other investigators[2–6] have commented that the echocardiogram reflects the degree of hypoplasia of the left-sided structures, but no systematic comparison has been attempted. We have extended these observations by comparing the anatomic dimensions of the mitral valve, left ventricle and aortic valve with measurements from M mode echocardiograms recorded during life in 18 infants with the hypoplastic left heart syndrome.

Comparisons of anatomic and echocardiographic findings: In all of our cases in which mitral valve echoes were recorded on M mode echocardiography, pathologic study revealed a patent mitral valve with an orifice diameter greater than 3 mm. In each of these cases, ventricular septal echoes were also present in the echocardiogram, and the anatomic left ventricular diameter measured 8 to 12 mm. When echoes from the mitral

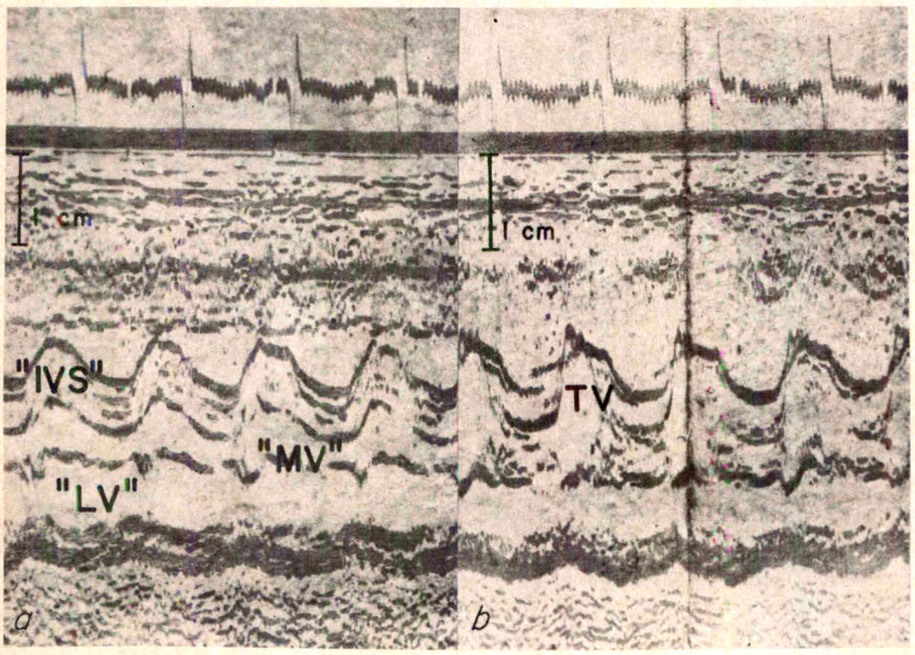

FIGURE 7. Case 16. Coexistent aortic and mitral atresia with blind hypoplastic mitral valve (case in which the echocardiogram was misinterpreted). **a,** echocardiogram initially interpreted as showing evidence of an identifiable left ventricular ("LV") chamber. "IVS" = ventricular septal echoes; "MV" = mitral apparatus. **b,** same case. Echocardiogram obtained with a slightly different transducer angulation, demonstrating that the echoes were actually produced by the tricuspid valve (TV) and its supporting apparatus.

valve were not identified, echoes of the ventricular septum were also absent. However, in such cases the mitral valve was not always atretic nor the left ventricle severely hypoplastic in the pathologic specimen. In four cases in which pathologic study revealed a mitral valve orifice greater than 3 mm and a left ventricular diameter of 8 to 12 mm, these structures were not identified echocardiographically. Three of these studies had been performed by an experienced echocardiographer. Failure to identify echoes from the mitral valve and ventricular septum in these four cases is not explained and may have resulted from a limited echocardiographic examination.

In each case in which echoes of the aortic valve were identified, the valve was patent in the pathologic specimen. In some of these the valve was stenotic. The valve was atretic in 9 of 11 cases in which echoes from the

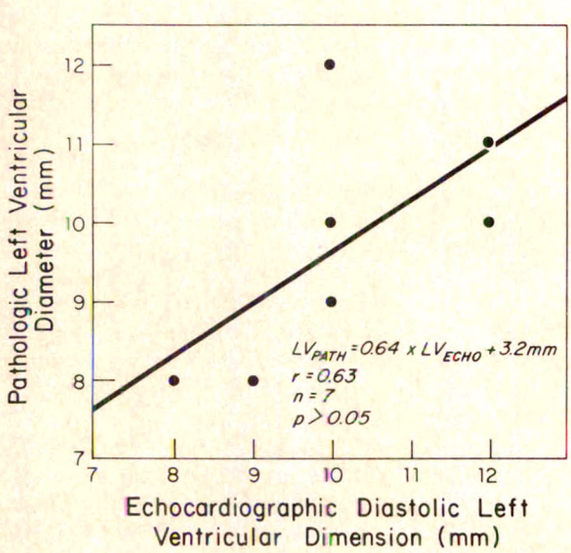

FIGURE 8. Linear regression analysis of the comparison of echocardiographic left ventricular dimension (LV_{ECHO}) and anatomic left ventricular diameter (LV_{PATH}). The correlation is not statistically significant in this small group of cases.

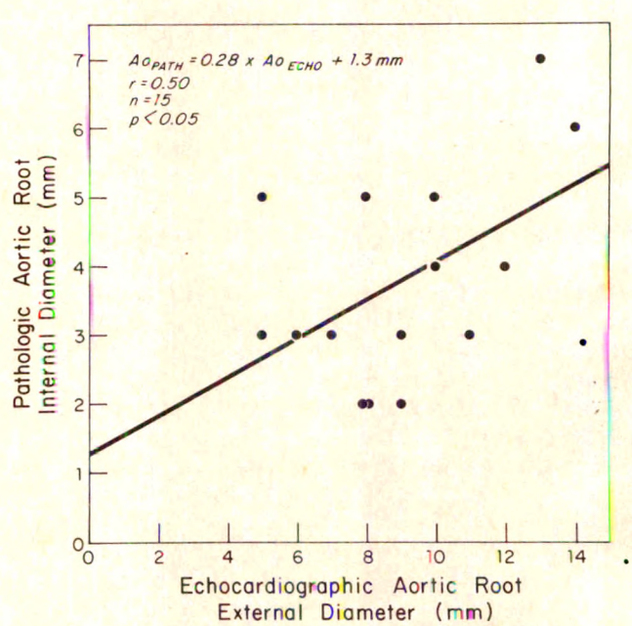

FIGURE 9. Linear regression analysis of the comparison of echocardiographic aortic root dimension (Ao_{ECHO}) and anatomic internal diameter of the aortic root (Ao_{PATH}). Although the correlation is statistically significant, sufficient scatter is present to prevent accurate prediction of aortic root size from the echocardiogram using these data.

aortic valve were not demonstrated in the echocardiogram.

Hypoplasia of mitral valve: When the mitral valve was recorded in the echocardiogram, its excursion had a statistically significant correlation with the anatomic diameter of the valve ($p < 0.05$). However, there were no cases intermediate between the six markedly hypoplastic mitral valves and the single larger valve, the latter associated with a common A-V canal deformity. It would be hazardous to attempt to predict the anatomic size of the orifice of the mitral valve from the echocardiographic excursion in other patients on the basis of these data. The echocardiographic excursion of the six hypoplastic mitral valves ranged from 3 to 5 mm. Our findings suggest that this range of excursion should be strongly suggestive of hypoplasia of the mitral valve.

Paradoxic anterior motion of echoes from the posterior mitral valve leaflet during diastole is a characteristic feature of acquired mitral stenosis and occurs commonly in congenital mitral stenosis not associated with coarctation of the aorta or a ventricular septal defect.[12] In our small group, this finding occurred in only two of six cases with a hypoplastic mitral valve. We detected no anatomic findings that might explain this echocardiographic difference between these cases and cases of hypoplastic mitral valve without paradoxic anterior motion.

Small left ventricular diameter: The measured anatomic diameter of the left ventricle did not have a statistically significant correlation with the echocardiographic diastolic left ventricular internal dimension. The lack of correlation might in part be explained if the echocardiographic and anatomic measurements were obtained from different diameters of the left ventricle. Because the pathologic specimen is not distended by blood and usually shrinks with fixation, the echocardiographic dimension would be expected to be larger than the anatomic diameter. This was not uniformly the case; thus the measurements in the specimen and in the echocardiogram may have been made from different portions of the left ventricle. Also, the echocardiographic dimensions may be in error because of problems with angulation caused by displacement of the small left ventricle.

Aortic atresia: Comparison of the echocardiographic and anatomic diameters of the aortic anulus yielded a statistically significant correlation ($p < 0.05$), but there was considerable scatter. Therefore, on the basis of our study, exact prediction of the size of the aortic valve anulus from the echocardiogram is not possible in an individual patient. The poor correlation in our cases may have been caused by tangential recording of the aorta by echocardiography, although all measurements were made when parallel wall movement was present.

The four echocardiographic studies performed by pediatric cardiology fellows were as reliable in detecting anatomically present structures as those performed by more experienced echocardiographers. Exclusion of these four studies from the statistical comparison of echocardiographic and anatomic measurements of aortic root size did not improve the correlation.

Proposed echocardiographic criteria: The following criteria have been proposed for the echocardiographic diagnosis of hypoplastic left heart syndrome[11]: (1) The mitral valve displays diminished excursion; (2) the left ventricular internal dimension is less than 10 mm; and (3) the aortic root dimension is less than 5 mm, with no evidence of echoes from aortic valve cusps. No single case in our series fulfilled all three of these criteria.

Our most sensitive echocardiographic measurement was an excursion of 5 mm or less of the mitral valve anterior leaflet or inability to detect the mitral valve on echocardiography. In five of the seven cases in which the left ventricle was recorded in the echocardiogram, the diastolic left ventricular internal dimension measured 10 to 12 mm, exceeding the proposed limit. None of our cases had an echocardiographic aortic root dimension of less than 5 mm. Solinger et al.[12] reported that 10 mm is the lower limit of normal for an aortic root dimension in infants in the body weight range of our patients. Six of our cases had an aortic root dimension in the cited normal range, although the pathologic specimen revealed that the aortic valve was markedly hypoplastic in three of the six and atretic in one. If all of these criteria are met, it is almost certain that hypoplastic left heart syndrome is present. However, some patients with this syndrome may not meet all of the criteria. Combining the findings from the echocardiogram with those from the clinical examination, electrocardiogram and roentgenogram will not always be sufficient to establish the diagnosis of hypoplastic left heart syndrome, and further invasive studies may be necessary in some patients.

Two dimensional echocardiography was not available during the period in which this study was performed. Lange et al.[13] have suggested that the lack of spatial orientation in M mode echocardiography causes a less accurate anatomic assessment of infants with hypoplastic left heart syndrome than is available from cross-sectional studies. Our initial experience tends to confirm this view, but the number of patients studied is too small for analysis.

Hypoplastic Left Heart Syndrome: Experience With Palliative Surgery

WILLIAM I. NORWOOD, MD, FACC*
JAMES K. KIRKLIN, MD*
STEPHEN P. SANDERS, MD†

Boston, Massachusetts

Aortic atresia is a form of hypoplastic left heart syndrome always complicated by associated severe hypoplasia of the ascending aorta and various degrees of mitral valve and left ventricular hypoplasia. At present it is a universally fatal lesion in early infancy. This is a report of a new palliative procedure for hypoplastic left heart syndrome that has resulted in early ongoing survival of two infants with aortic atresia. On the basis of experience with a third patient, an operation for future physiologic correction is proposed.

Prolonged survival after either palliative or reparative surgery for hypoplastic left heart syndrome has not been reported. The anatomic complexity of this cardiac malformation has been considered prohibitive of long survival, with or without surgery, and generally only supportive therapy has been recommended. However, persistent effort to improve the long-term outlook of neonates with hypoplastic left heart syndrome is to be encouraged for at least three reasons: (1) It is the fourth most common congenital cardiac anomaly entering the New England Regional Infant Cardiac Program (after ventricular septal defect, tetralogy of Fallot and transposition of the great arteries) and accounts for nearly 25 percent of cardiac deaths during the 1st week of life and 15 percent of cardiac deaths during the 1st month of life.[1] (2) Unlike many forms of congenital cardiac disease, the syndrome has a very low incidence rate of associated extracardiac anomalies.[1,2] (3) In principle, hypoplastic left heart syndrome is similar to tricuspid atresia and other forms of univentricular heart in which the outlook after surgical intervention has recently improved dramatically.[3,4] This report constitutes our experience with the development of effective palliation for infants with hypoplastic left heart syndrome.

Case Reports

Case 1: This infant, a 2.9 kg product of a full-term, uncomplicated pregnancy, was noted to have cyanosis, tachypnea, hepatomegaly and cardiac enlargement shortly after birth. Cardiac catheterization revealed a hypoplastic left ventricle, aortic atresia and a large patent ductus arteriosus (Fig. 1). Arterial P_{O_2} (partial pressure of oxygen) on 100 percent oxygen was 24 to 33 torr with normal partial pressure of carbon dioxide (P_{CO_2}) and pH. The patient was transferred to an outside hospital but returned 1 month later.

Physical examination revealed a cyanotic infant weighing 3.39 kg. The heart rate was 152 beats/min and the respiratory rate 58/min. Cardiac examination revealed a quiet precordium, single second heart sound and a grade 2/6 systolic murmur at the apex. The electrocardiogram showed an axis of +120° and right ventricular hypertrophy with "strain."

The following operative procedure was performed: November 8, 1977, when the infant was 5 weeks old, with use of deep hypothermia and circulatory arrest, (1) enlargement of the atrial septal defect, (2) a modified Glenn shunt (end to side right pulmonary artery to superior vena cava anastomosis), (3) ligation of

the patent ductus arterious, (4) left pulmonary arterial banding, and (5) side to side anastomosis of the aorta and main pulmonary artery using the right pulmonary artery to extend the angioplasty. During the early postoperative period, left atrial and right atrial pressures were 9 to 10 mm Hg and arterial pressures were 80 to 90 mm Hg with normal sinus rhythm and a heart rate of 130 beats/min. Marked arterial desaturation persisted, however, and the patient died with progressive acidosis and hyperkalemia 7 hours after operation.

Case 2: This infant, a 2.9 kg product of a full-term uncomplicated pregnancy, was referred on January 19, 1979 at age 36 hours because of severe cyanosis and acidosis. Physical examination revealed a cyanotic infant with a pulse rate of 160 beats/min, respiratory rate of 80 to 100/min and a systolic blood pressure in all limbs of 50 mm Hg. There were diffuse rales bilaterally. The chest roentgenogram showed cardiac enlargement with moderate pulmonary vascular congestion. The electrocardiogram revealed an axis of +120°, right atrial enlargement and right ventricular hypertrophy.

Cardiac catheterization demonstrated aortic atresia, a large patent ductus arteriosus, left superior vena cava to coronary sinus, mild hypoplasia of the left ventricle with a large ventricular septal defect and no significant mitral stenosis or regurgitation (Fig. 2).

Operations: On January 20, at age 3 days, with use of both a left thoracotomy and median stenotomy, a 10 mm Dacron® graft was placed from the proximal main pulmonary artery to the descending aorta. The patent ductus arteriosus was ligated and a band was placed around the main pulmonary artery distal to the graft. A second cardiac catheterization on January 31, performed because of persistent respiratory insufficiency, revealed occlusion of the origin of the right pulmonary artery by the band (Fig. 3). On February 6, with the infant under deep hypothermia and total circulatory arrest, a 12 mm valved conduit was placed from the right ventricular outflow tract to the descending aorta and the pulmonary artery band was moved to the repaired proximal main pulmonary artery.

Postoperatively, while hemodynamically stable, she required prolonged intermittent ventilator support and had nutritional insufficiency with gastrointestinal feeding intolerance. Prolonged intravenous hyperalimentation was required, with consequent Staphylococcus epidermidis septicemia requiring long-term antibiotic therapy. The patient is now 5 months old and has a satisfactory hemodynamic, respiratory and nutritional status.

Case 3: This infant, a 3.7 kg product of a full-term pregnancy by cesarean section, was transferred at age 2 days with findings of a heart murmur, cyanosis, decreased peripheral pulses and an echocardiographic diagnosis of hypoplastic left heart. Physical examination revealed a cyanotic infant with a heart rate of 150 beats/min, a respiratory rate of 80/min, mean blood pressure of 55 mm Hg in the arms and diminished peripheral pulses. There was a single second heart, a ventricular gallop sound and a grade 3/6 systolic ejection murmur. The chest roentgenogram revealed mild cardiac enlargement with increased pulmonary blood flow. The electrocardiogram disclosed a QRS axis of +50°, right atrial enlargement and right ventricular hypertrophy. Cardiac catheterization demonstrated aortic atresia, mitral atresia, a patent ductus arteriosus and a 20 mm Hg pressure gradient from the right ventricular sinus to descending aorta. The patient was resuscitated with a continuous infusion of prostaglandin E_1 and intermittent doses of sodium bicarbonate.

On March 3, at age 3 days, a 12 mm valved external conduit was anastomosed to the descending aorta through a left thoracotomy. Through a median sternotomy, using deep hypothermia and circilatory arrest, the proximal end of the conduit was anastomosed to the right ventricular outflow tract (Fig. 4). The ductus arteriosus was ligated and the main pulmonary artery banded. Postoperatively the infant received intravenous infusion of dopamine (5 μg/kg per min) and nitroprusside (5 μg/kg per min) for 3 days and was extubated on the 5th postoperative day. She was released from the hospital on the 24th postoperative day, feeding well, gaining weight and clinically well.

Discussion

Hypoplastic left heart syndrome: Aortic atresia or stenosis, atresia or interruption of the aortic arch, severe

stenosis or atresia of mitral valve and a small left ventricle compose a constellation of defects initially termed "hypoplasia of the aortic tract complexes" by Lev[5] in 1952 and later called hypoplastic left heart syndrome by Noonan and Nadas.[1] Among these, aortic atresia is uniquely complex and although numerous proposals have been reported, no effective management protocol has been established.[6–8] The central anatomic feature of each of the three patients in this report is aortic atresia, which is always complicated by associated severe hypoplasia of the ascending aorta and various degrees of mitral valve and left ventricular hypoplasia. When a large ventricular septal defect is present, as in Case 2, mitral valve and left ventricular hypoplasia may be mild. In a review of 172 patients with aortic atresia, Moodie et al.[7] identified 12 patients (7 percent) with an associated large ventricular septal defect. However, in 60 percent of cases the ventricular septum is intact and the mitral valve hypoplastic, allowing no egress of blood from the left ventricle, which remains diminutive with vacuolization of the subendocardial layer and development of large myocardial sinusoids. Aortic atresia and mitral atresia with no discernible left ventricle occur in combination in about one third of patients.

Prognosis: Perinatal survival is dependent on maintenance of the systemic circulation through a patent ductus arteriosus and on adequate pulmonary venous return, most commonly through an interatrial communication (usually a patent foramen ovale). Neonatal death usually results from inadequate coronary and systemic perfusion secondary to high pulmonary to systemic flow ratios with severe congestive heart failure or closure of the ductus arteriosus, or both. Less commonly, death results from hypoxemia and pulmonary venous congestion secondary to a restrictive interatrial communication. While a lone child with aortic atresia survived to age 3.5 years,[7] the reported mean survival time ranged from 4 to 23 days.[1,7]

Because of this high neonatal mortality rate, any systematic approach aimed at improving long-term survival for neonates with hypoplastic left heart syndrome requires early recognition and definition of pertinent anatomic features with cardiac catheterization and echocardiography (including the presence of aortic atresia, the presence or absence of a large ventricular septal defect, the size of the interatrial communication, the status of the mitral valve and the presence and location of coarctation of the aorta[9]). This should be followed, if necessary, by resuscitation with balloon atrial septotomy and prostaglandin E_1 infusion to maintain ductal patency in preparation for early surgical intervention.

Surgical considerations: Except in the presence of an associated large ventricular septal defect and two well developed ventricles, physiologic correction of aortic atresia is possible only by the separation of the pulmonary and systemic circulations using the right ventricle as the systemic pumping chamber. The feasibility of utilizing the right atrium as the pulmonary pumping chamber has been established both experimentally and clinically,[10,11] but requires near normal

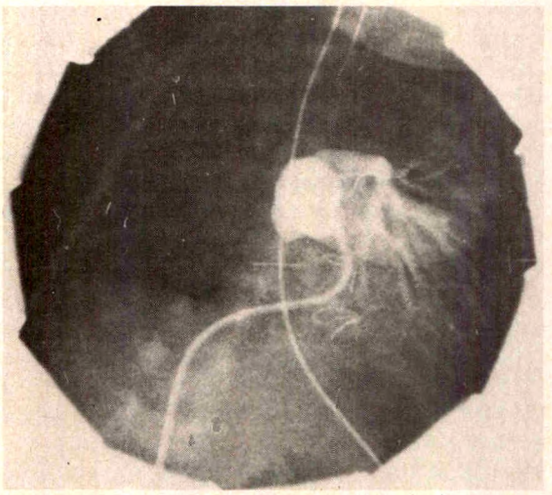

FIGURE 3. Case 2. Frame from anterior-posterior postoperative cineangiogram with injection into the main pulmonary artery filling the conduit and the left pulmonary artery. The right pulmonary artery is occluded by the pulmonary arterial band.

adult pulmonary vascular resistance with a mean pulmonary arterial pressure of less than 20 mm Hg and normal ventricular end-diastolic pressure. In the newborn period, however, pulmonary vascular resistance is elevated and may not decrease to adult levels until the infant is 6 to 8 weeks of age.[2] Furthermore, a postmortem quantitative pulmonary morphometric analysis by Heidelberger et al.[12] of neonates with the hypoplastic left heart syndrome demonstrated pulmonary vascular

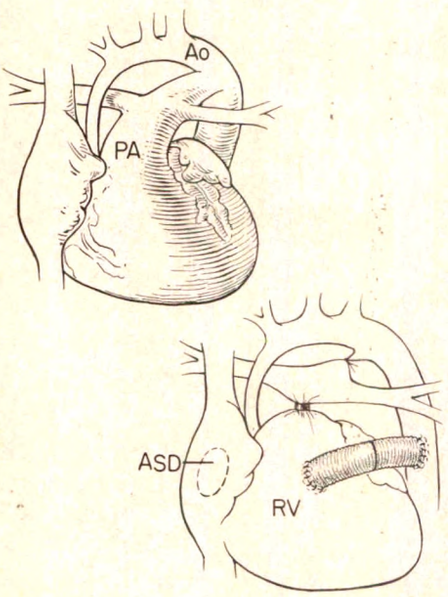

FIGURE 4. Case 3. Artist's conception of aortic atresia (**top**) and palliative procedure (**bottom**). Lower rendition illustrates ligation of patent ductus arteriosus, band on the main pulmonary artery (PA) and valved conduit between the right ventricular (RV) outflow tract and the descending aorta. Ao = aorta; ASD = atrial septal defect.

changes (including extension of smooth muscle into distal pulmonary arteries, increased wall thickness of distal arteries and slightly decreased arteriolar to alveolar ratio) that are likely to result in elevated pulmonary vascular resistance. Because pulmonary vascular resistance is expected to be high in the neonate with hypoplastic left heart syndrome, we now consider a multistage approach most likely to produce long-term survival.

Multistage surgical approach: *The principles of the first stage include* (1) establishment of a permanent communication between the right ventricle and aorta, (2) limitation of pulmonary blood flow to attenuate the pulmonary vascular changes secondary to elevated pulmonary blood flow and pressure, and (3) insurance of a satisfactory interatrial communication in the presence of mitral valve hypoplasia or atresia. Two attempts, by Cayler et al.[13] and Freedom et al.,[13] at surgical palliation incorporated these principles using a Waterston shunt in a neonate with critical aortic stenosis[13] and a Potts shunt in a child with aortic atresia and ventricular septal defect.[8] Both procedures were followed by right and left branch pulmonary arterial banding. The palliative effects lasted 7 and 16 months, respectively. However, the difficulty in achieving limited and bilaterally balanced pulmonary blood flow and the risk of anatomic distortion of the distal pulmonary arteries make branch pulmonary artery banding undesirable.

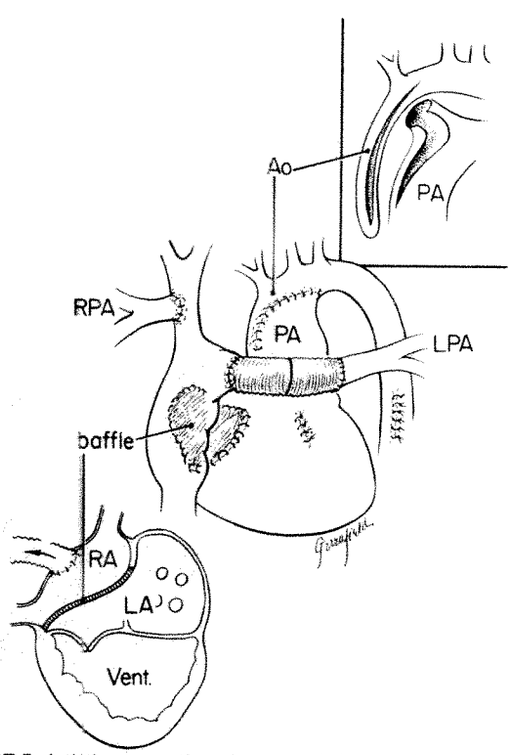

FIGURE 5. Artist's conception of proposed physiologic repair of aortic atresia (stage 2). The main pulmonary artery (PA) and the aorta (Ao) are anastomosed using the proximal stump of the right pulmonary artery (RPA) (**upper panel**). The right pulmonary artery is anastomosed end to side with the superior vena cava and a valved conduit placed between the right atrium (RA) and left pulmonary artery (LPA). An interatrial baffle ensures filling of the right ventricle (Vent.) with pulmonary venous blood from the left atrium (LA). A schematic drawing of the baffle and conduit is shown in the **lower panel.**

Litwin et al.[14] avoided branch pulmonary arterial banding by placement of a nonvalved conduit from the main pulmonary artery to the descending aorta and placing a band on the main pulmonary artery distal to the conduit in four infants with an interrupted aortic arch. The one survivor manifested not only severe distortion of the pulmonary architecture by the distal pulmonary arterial band but also pulmonary vascular obstructive disease.

On the basis of the experience reported here, we propose that a more satisfactory means of accomplishing the palliative goals outlined is placement of a valved conduit from the right ventricular free wall to the descending aorta allowing ample room for the standard placement of a pulmonary arterial band on the main pulmonary artery (Fig. 4). This can be accomplished by end to side anastomosis between the valved conduit and descending aorta through a left thoracotomy incision using a partially occluding clamp. After placing the conduit entirely within the left chest, the thoracotomy incision is closed and the patient repositioned for a median sternotomy. Cardiopulmonary bypass is established by cannulation of the main pulmonary artery for arterial inflow through the ductus arteriosus and cannulation of the right atrial appendage for venous return. The branch pulmonary arteries are occluded during the cooling phase and, with use of deep hypothermic circulatory arrest the proximal end of the conduit is anastomosed to the right ventricular outflow tract. The atrial septal defect may be enlarged if necessary. The ductus arteriosus is ligated and the main pulmonary artery is banded after discontinuation of cardiopulmonary bypass. This approach was used on a 2 day old boy (Case 3) with aortic and mitral atresia who was released from the hospital on the 24th postoperative day and is now clinically well at age 3 months.

The second stage of the surgical approach, subsequent physiologic correction of this lesion, is dependent on separation of the systemic and pulmonary circulations. Although many procedures have been proposed,[6,8,15,16] we believe that utilization of autologous valve and vascular tissue in the systemic circulation and a valved external conduit for the pulmonary circuit maximize both simplicity of technique and potential for growth (Fig. 5). As demonstrated in Case 1, anterograde flow through the ascending aorta can be established by side to side anastomosis of the pulmonary artery and diminutive ascending aorta using a portion of the right branch pulmonary artery (upper panel, Fig. 5). An interatrial baffle is constructed to provide continuity between the left atrium and tricuspid valve through an atrial septal defect. The pulmonary arterial circulation can be completed by anastomosis of the distal right pulmonary artery to the superior vena cava and placement of a conduit from the right atrium to the left pulmonary artery (Fontan procedure). When a large ven-

tricular septal defect and left ventricle coexist, the left ventricle can be used for the systemic circulation by connecting the ventricular septal defect and pulmonary artery with an interventricular baffle while the palliative valved conduit on the right ventricular outflow tract is transferred from the descending aorta to the distal pulmonary artery. In these cases the atrial septal defect is merely closed.

Particularly in patients with aortic atresia and intact ventricular septum, this physiologic repair requires both low pulmonary vascular resistance and minimal secondary changes of the pulmonary architecture from palliative surgery. Available experimental and clinical evidence suggests that early smooth muscle alterations in pulmonary arterioles, secondary to a large left to right shunt, are reversible after adequate pulmonary arterial banding.[17] Because normal pulmonary vascular resistance is expected after several months and because secondary changes from the pulmonary band may occur after 1 year, the current plan is to perform repair in these two children before they are 1 year of age. The ultimate efficacy of these procedures remains to be demonstrated, but early results of stage I palliation in our two patients are encouraging.

Total Anomalous Pulmonary Venous Connection in Infancy: Influence of Age and Type of Lesion

KEVIN TURLEY, MD
WILLIAM Y. TUCKER, MD
DANIEL J. ULLYOT, MD, FACC
PAUL A. EBERT, MD, FACC

San Francisco, California

The factor of age has been proposed as the major determinant of survival after correction of total anomalous pulmonary venous connection; consequently, operation may be postponed and the infant's clinical condition deteriorate. This study describes 22 infants who underwent surgical correction of this disorder in the 1st year of life between 1975 and 1978. Twelve were in the 1st month and six in the first 4 days of life. Nine had a type I, six a type II, six a type III and one a type IV lesion. The infants' weights ranged from 2.6 to 6.9 kg (mean 4.0) at the time of operation; this fact emphasizes the retarded growth of these infants.

Nineteen of 22 infants (including all 6 infants operated on during the first 4 days of life) survived operation, yielding an 87 percent hospital survival rate. Two late deaths occurred secondary to intimal fibroplasia of the pulmonary veins proximal to the site of atrial anastomosis; this represents a potential problem especially in infants with type III lesions. The strongest determinants of survival were type of lesion, pulmonary venous obstruction and depressed left ventricular function. Age in itself is not a determinant of survival after correction of total anomalous pulmonary venous connection. The timing of corrective surgery should be influenced by the clinical condition of the infant.

Total anomalous pulmonary venous connection represents one of the few forms of congenital heart disease in which the valves and ventricles are usually normal and thus its correction should offer excellent long-term results. Although this disorder represents only 1 or 2 percent of congenital cardiac lesions, if untreated, the resultant mortality in the 1st year of life is greater than 80 percent, with only 5 percent of patients asymptomatic at that time.[1–3] The majority of these patients present at the point of death in the early weeks of life.

Anomalous pulmonary venous return has been classified according to site of the anomalous connections: type I, supracardiac; type II, cardiac; type III, subdiaphragmatic; and type IV, mixed lesions.[1] Various determinants of survival for both medically and surgically treated patients have been proposed in the past. These include the type of lesion, presence of pulmonary venous obstruction, left atrial and left ventricular size and left atrial and left ventricular volume and function. However, age at the time of operative therapy has been the most consistently cited determinant of survival. As a result, postponement of attempts at surgical correction, risking the subsequent deterioration of the infant's condition, has been considered justified.[4–7]

Methods

Patients: From January 1975 through January 1979, a total of 22 patients with total anomalous pulmonary venous connection aged 1 day through 11 months underwent corrective surgery at the University of California, San Francisco. Twelve of these infants were in the 1st month of life and six were less than 4 days of age (Fig. 1). There were 15 male and 7 female infants; they ranged in weight

from 2.6 to 6.9 kg (mean 4.0), in height from 37 to 68 cm (mean 53.5) in and body surface area from 0.15 to 0.35 cm^2 (mean 0.22 cm^2). Nine of the 10 patients older than 1 month of age were in the lowest 1 percentile or less for growth (standard deviation 2.5). The remaining infant was in the lowest 5th percentile (standard deviation 1) (Fig. 2).

Type of lesion: Nine patients had a type I lesion, with return to the azygos vein in one (Case 8) and to the right superior vena cava in one (Case 9); six patients had a type II lesion, with return directly to the right atrium in one (Case 15); six patients had a type III lesion and one a mixed lesion (type IV) with the left pulmonary veins entering a left anterior cardinal vein and the right pulmonary veins the coronary sinus (Table I). More than half of the patients presented with evidence of pulmonary venous obstruction, including all six of those with a type III lesion. The criteria for obstruction were a pulmonary capillary wedge pressure greater than 12 mm Hg and a gradient at the pulmonary to systemic connection or angiographic demonstration of obstruction (Table I).

Among patients with a type I lesion, a gradient at the left superior vena caval junction of 12, 10 and 6 mm Hg was noted in Patients 2, 3 and 7, respectively. In Patient 8 a gradient of 36 mm Hg was present at the azygos connection. In each, persistence of contrast medium during the levophase of the angiogram was also noted.

Among patients with a type II lesion, Patients 12 and 14 demonstrated a gradient of 12 and 6 mm Hg, respectively, although no angiographic confirmation of obstruction was obtained. In these cases the gradient may have represented

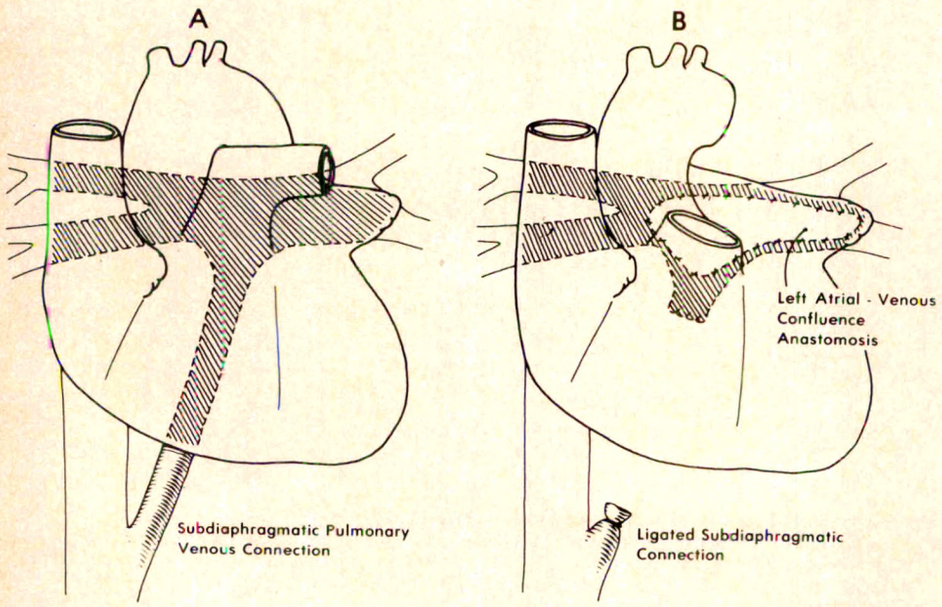

FIGURE 5. Type III total anomalous pulmonary venous connection. **A**, subdiaphragmatic connection to inferior vena cava. **B**, method of repair.

a flow phenomenon. In Case 10 the pulmonary venous pressure was 9 mm Hg at cardiac catheterization at age 2 days; however, a markedly narrowed orifice was observed at operation at age 11 days.

Among patients with a type III lesion, a pulmonary capillary wedge pressure of 24, 20, 20 and 24 mm Hg was observed in patients 16, 19, 20 and 22, respectively, as well as angiographic demonstration of obstruction (Table I). In Patients 17 and 18 no wedge recordings could be obtained; however, clear angiographic evidence of obstruction was present. Finally, in the single infant with a mixed lesion, contrast medium persisted in the long tortuous left superior vena caval connection, suggesting unilateral obstruction. The remaining infants presented with severe congestive heart failure.

Cardiac catheterization data: Pulmonary arterial pressure was elevated in 16 patients (mean 40.5 mm Hg). The pulmonary arterial to systemic arterial mean ratio was 0.87, mean pulmonary resistance was 6.72 units and the pulmonary to systemic flow ratio was 1.5:1. Angiographic assessment revealed decreased left atrial volume in all but five infants and decreased left ventricular volume in five. Decreased left ventricular function was noted in only two infants, as assessed by angiographic evaluation of ejection fraction from the right anterior oblique projection of each biplane cineangiogram. This method avoids inclusion of the effect of paradoxic septal motion produced by right ventricular overload in this condition. In addition, echocardiographic evaluation of ejection fraction was recorded in the last 15 infants treated. By means of these techniques normal to hyperdynamic function (ejection fraction greater than 0.50) was noted in all infants except in Case 14 (ejection fraction 0.24) and Case 18 (ejection fraction 0.35).

Surgical techniques: Cardiopulmonary support during the operative procedure included the technique of surface-induced deep hypothermia and total circulatory arrest in 7 patients and cardiopulmonary bypass hypothermia and reduced flow in 15. In small infants both techniques were facilitated with the use of single atrial cannulation for venous return.

Surgical correction was accomplished utilizing venous ligation, mobilization of the venous confluence and left atrial to pulmonary confluence anastomosis in infants with a type I or type III lesion. Care was taken to produce maximal cross-sectional area in the anastomosis by extending the incision in the posterior left atrial wall from the atrial septum to the tip of the left atrial appendage. An interrupted continuous anastomosis with 6–0 monofilament was used in each case, with care taken to avoid any purse-string effect. A pericardial baffle was used in infants with a type II lesion as well as in the one infant with a mixed lesion. Care was taken in these cases to use delicate superficial suture technique and a loose billowing pericardial baffle. A segment of tissue between the central septal defect and the orifice of the coronary sinus was excised to further augment the communication. In one case a piece of pericardium was returned to the posterior left atrial wall to enlarge the chamber and facilitate the anastomosis. Figures 3, 4 and 5 illustrate in detail the types of lesions and the operative corrections used.

Postoperative care involved close observation of the physical findings in these patients as well as correction, as indicated, of decreased oxygenation, perfusion or volume status.

Results

Twenty-two patients aged 1 day to 11 months were operated on, with 19 hospital survivors (Table II). The hospital survival rate for the total group was 87 percent and 84 percent in infants less than 1 month of age. All six infants in the first 4 days of life were among the survivors. The three hospital deaths occurred in a 12 day old infant (Case 18) with a type III lesion who presented with severe pulmonary venous obstruction and respiratory distress; a 3 month old infant at the point of death (Case 21) with a type III lesion and severe obstruction (as evidenced by a pulmonary wedge pressure of 24 mm Hg with a right atrial pressure of 4 mm Hg); and a 17 day old infant (Case 14) with a type II lesion who had depressed left ventricular function both preoperatively and after repair.

In two patients with a type III lesion (Cases 17 and 19) pulmonary venous obstruction developed proximal to the atrial anastomosis 3 months postoperatively. These patients underwent patch angioplasty to the distal pulmonary veins and, although this was initially successful, stenosis subsequently recurred (Fig. 6).

TABLE II

Postoperative Survival by Anatomic Type of Lesion

Type of Lesion	Number of Patients	Mortality		Hospital Survival (%)
		Early	Late	
I	9	0	0	94
II	6	1	0	
IV	1	0	0	
III	6	2	2*	67

* Late obstruction of the pulmonary veins proximal to the anastomosis.

Discussion

Role of age as a determinant of operative survival: Wukasch et al.[6] proposed age as a major determinant of survival in surgical correction of total anomalous pulmonary venous connection.[6] They found that correction in patients older than 1 year carried a hospital mortality rate of approximately 30 percent, whereas the rate was greater than 50 percent in younger patients.[6] Thus, because older children appeared to have a lower operative risk, operative intervention was often postponed in the hope of improving result. Unfortunately, this policy fails to take into account not only the unstable condition in early life of untreated patients, but also the mortality of the infants not operated on. If operation is postponed and the patient becomes symptomatic, the mortality rate without operation approaches 90 percent in the 1st year of life. This high rate results from a high incidence in the infant group of pulmonary venous obstruction, which is often associated with an inadequate atrial septal defect. Progressive cyanosis, acidosis and congestive heart failure are usually not reversible without surgical intervention. These symptoms occur because of decreased left ventricular filling, reduced systemic output, right heart failure and congestion of the lungs. In those patients without pulmonary venous obstruction or pulmonary vascular disease during infancy, correction can

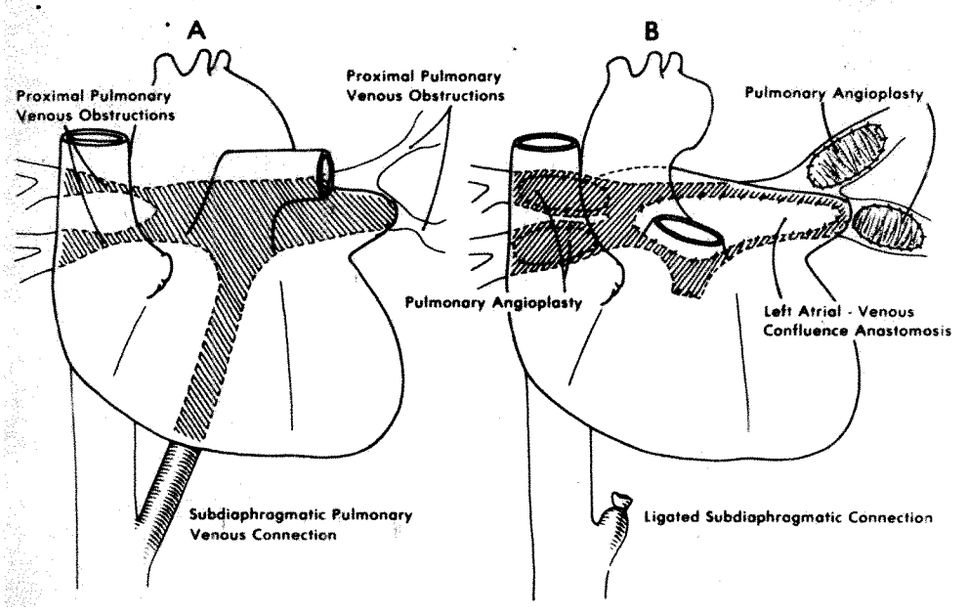

FIGURE 6. A, type III total anomalous pulmonary venous connection with primary pulmonary venous stenosis. **B,** patch angicplasty of pulmonary veins.

be accomplished on an elective basis. However, the majority of patients do not experience this favorable course.

Role of pulmonary venous obstruction and balloon septostomy: Symptoms of pulmonary venous obstruction can result from obstruction at either the venous level or the atrial septal level due to closure of the atrial septal defect. Balloon atrial septostomy at cardiac catheterization can often result in improvement in patients with type I or type II lesions. In these patients, left ventricular filling is restricted by a decrease in interatrial communication. In patients with type III lesions, although a septostomy should be attempted, a successful result is less common because obstruction often occurs at the infradiaphragmatic venous level.

Operative mortality for early surgical correction: An early appreciation of the severity of the obstruction and lack of improvement with balloon atrial septostomy should result in earlier intervention and correction for survival. Early operative correction once symptoms develop has been shown to improve survival.[8] Our series demonstrates that a low mortality can be achieved with operative correction of total anomalous pulmonary venous connection, even when infants are at the point of death. This correction should be initiated at the earliest presentation of symptoms. Only 1 of the 16 infants with a type I, type II or mixed lesion died (6 percent mortality rate, Table II). The one infant with a type II lesion demonstrated depressed preoperative left ventricular function, although atrial and left ventricular size appeared adequate. Although the patient could be weaned from cardiopulmonary support, progressive left ventricular failure occurred. It appeared that poor preoperative left ventricular contractility of unknown cause existed and that improved oxygenation and increased left-sided filling pressure did not improve left ventricular performance. Type III lesions presented a difficult problem. The two remaining operative deaths occurred in infants with this lesion. Further, all six infants with a type III lesion had preoperative pulmonary venous obstruction. In the two fatal cases, one infant was at the point of death at the time of operation and could not be weaned from cardiopulmonary support. The other had experienced multiple episodes of bradycardia before repair; after repair and successful weaning from cardiopulmonary bypass this infant experienced an additional episode of sinus bradycardia with cardiac arrest. Postmortem studies demonstrated subarachnoid hemorrhages, which may have been responsible for this patient's bradyarrhythmia.

Late postoperative results: In two infants with a type III lesion obstruction in the pulmonary veins subsequently developed that was not related to the suture lines. Such a process has been noted in previous series.[8–10] The usually thicker common channel wall found in the area of confluence of the pulmonary veins may have contractile tissue similar to that of the ductus arteriosus, causing progressive narrowing and possible obliteration with arterial fibroplasia of the pulmonary veins. Because of the previous higher mortality in infants with a type III lesion few patients are available for long-term follow-up study and few long-term postrepair angiograms are available for comparison. However, a progressive narrowing of the subdiaphragmatic channel has been thought to be responsible for the fulminant, progressive pulmonary venous obstruction seen in this group; an extension of this process into the pulmonary veins could have been responsible for the late pulmonary venous obstruction in our two older infants because the opening into the left atrium was large in both patients, with the obstruction existing in the pulmonary veins themselves. This process may not be unique to infants with a type III lesion; Wright et al.[4] described such late proliferative obstruction in two patients with

a type II lesion in their series. However, such lesions have rarely been noted. Thus, this represents a complication possible in all types of total anomalous pulmonary venous connection but more commonly encountered in type III lesions.[4,8–11]

Determinants of postoperative survival: A review of the specific determinants of survival in our infant group reveals that the type of lesion correlates highly with risk; two of three early deaths and both late cardiac deaths occurred in patients with a type III lesion. Likewise, the presence of obstruction, observed in all six patients with a type III lesion, was noted in all five infants who died postoperatively. Further, although pulmonary hypertension was seen in all groups (mean 40.5 mm Hg) the mean pressure was consistently greater than 50 mm Hg in all patients with a type III lesion.[8] Pulmonary to systemic flow ratio, although 1.00 or greater in all six patients with a type III lesion, did not correlate well with increased pulmonary vascular resistance. Left ventricular function was normal by angiographic and echocardiographic criteria in all but two patients. Both had low cardiac output postoperatively and are among the three who died after operation.[13] Finally, pulmonary to systemic flow ratio and left atrial and left ventricular size at catheterization were poor predictors of survival in this group.[4,12–14]

The results of this series demonstrate that total anomalous pulmonary venous connection can be corrected in early infancy.[4,8,9,15] The major determinants of survival in young infants are the type of lesion, the presence of preoperative pulmonary venous obstruction and deterioration of left ventricular performance.

Spectrum of Cardiovascular Lesions in Mucocutaneous Lymph Node Syndrome: Analysis of Eight Cases

JUNICHIRO FUKUSHIGE, MD
MICHAEL R. NIHILL, MB, MRCP, FACC
DAN G. McNAMARA, MD, FACC

Houston, Texas

Eight cases of mucocutaneous lymph node syndrome with cardiovascular complications are described. The clinical presentation in all but one patient conformed to the previously described features of this syndrome. Five patients had cardiac enlargement, six had electrocardiographic abnormalities and three had a murmur of mitral insufficiency. Each of the four patients who died had aneurysms of the coronary arteries, usually associated with organizing thrombi. In addition to involvement of the coronary arteries, the renal, mesenteric, vertebral, splenic, hepatic and iliac arteries were affected in individual cases. One patient required triple aortocoronary bypass surgery and one patient underwent excision of a brachial arterial aneurysm. Further long-term follow-up studies of the patients who have survived the acute stage of the syndrome are indicated to establish the spectrum of late complications and sequelae.

Mucocutaneous lymph node syndrome is now a well established clinical entity affecting mainly infants and young children.[1] The clinical features include a prolonged or intermittent fever, sterile conjunctivitis and diffuse reddening of the oral and pharyngeal mucosa with redness and fissuring of the lips. Later in the course of the fever there is redness and induration of the palms, soles, fingers and toes, followed by desquamation. There is also a polymorphous exanthema of the trunk and limbs with a nonpurulent cervical lymphadenopathy.

As originally described by Kawasaki[2] in 1967, the syndrome was thought to be a benign, transient febrile illness of children, limited geographically to Japan; a recent review[2a] by the committee on mucocutaneous lymph node syndrome in Tokyo has collected more than 15,000 cases in Japan alone. However, reports from the American continent,[3–5] Europe,[6–13] Australia[14] and other parts of Asia[15,16] and the Pacific[17] have emphasized the ubiquity of this disease. Previously reported cases of infantile periarteritis nodosa bear a striking similarity to mucocutaneous lymph node syndrome in both clinical and pathologic features.[4,18,19]

The pathologic basis of this disease is a nonspecific vasculitis initially involving the microvasculature of all parts of the body; after 10 days or so, manifestations of an endarteritis of the vasa vasorum of the major arterial branches of the aorta start to appear, particularly in the coronary arteries, brachiocephalic vessels, celiac axis and renal and iliofemoral vessels. The arteritis involves the intima and adventitia of these vessels and results in aneurysm formation, local obstruction and distal platelet embolization with distal ischemia or gangrene, rupture of the aneurysm or asymptomatic healing.

The increased clinical awareness of this syndrome in its acute phase and more frequent reports of coronary arterial aneurysms or myocardial infarction in young children have made a cardiologic evaluation part of the investigation of infants and children with prolonged, obscure febrile illnesses.[20,21] Recent reports of this syndrome[22] have emphasized in-

volvement of the coronary arteries, with few references to the sequelae of the panvasculitis in other parts of the body.

We present our experience with eight patients with mucocutaneous lymph node syndrome seen at Texas Children's Hospital between 1959 and 1978 to highlight the varied and diffuse nature of the cardiovascular lesions in this syndrome.

Clinical Material

From 1959 to 1978 at Texas Children's Hospital we have seen eight cases of mucocutaneous lymph node syndrome with cardiovascular complications. Five of these were diagnosed clinically and three were collected from the autopsy files. The clinical data, laboratory and pathologic findings of these eight cases are summarized in Tables I and II.

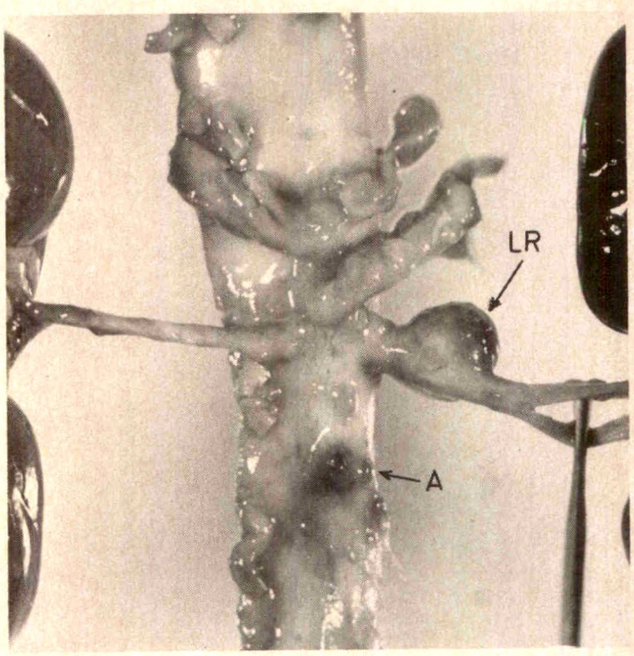

FIGURE 2. Case 8. Postmortem close-up view of the aorta and renal arteries showing an aneurysm measuring 0.7 cm in diameter at the origin of the left renal artery (LR, **arrow**). The right renal artery is not patent to probing, although no gross abnormality is seen externally. There is an aneurysm of the aorta measuring 0.4 cm in diameter (A, **arrow**) 1 cm distal to the origin of the renal arteries.

TABLE I

Clinical and Laboratory Features of Eight Patients With Mucocutaneous Lymph Node Syndrome

Case no.	Sex	State or Country	Race	Fever: Age at Onset	Fever: Duration	Sterile Conjunctivitis	Stomatitis	Reddening of Limbs	Induration of the Limbs	Desquamation From Fingertips

* An American-born Pakistani infant.

Clinical features: The eight patients include seven white children and one American-born Pakistani infant; four were male and four female. The clinical presentation in all but one patient (Case 8) conformed to the previously described features of this syndrome.[1,2] Five patients had cardiac enlargement, six had electrocardiographic abnormalities and three had the murmur of mitral insufficiency. Clinical laboratory data were not specifically diagnostic. Of five patients with data available, all had polymorphonuclear cell leukocytosis and anemia. Cerebrospinal fluid abnormalities were found in three of four patients studied and the erythrocyte sedimentation rate was elevated in the four patients in whom this test was performed. Of four patients studied, all had a diminished serum albumin and elevated alpha-2 globulin levels. IgE

values were not determined during the acute phase in any patient.

All eight patients had some overt cardiovascular abnormality. These abnormalities were confirmed at postmortem examination in four patients and by surgery in two (Cases 5 and 6). Five of eight patients (Cases 2 and 5 to 8) underwent angiographic examination. Each of the four patients who died (Cases 2, 3, 4 and 8) had aneurysms of the coronary arteries usually associated with organizing thrombi and one had a ruptured aneurysm. In addition to the coronary arteries, the renal, mesenteric, vertebral, splenic, hepatic, iliac and femoral arteries were affected in individual patients (Table II and Figs. 1 to 9).

Case 8: This case was unique because of complete absence of the usual clinical findings of a previous febrile illness, but the pathologic findings were consistent with the mucocutaneous lymph node syndrome. The patient, one of twins, was a 4 month old white female infant, born to a 26 year old white woman (gravida I, para II, abortion 0) by elective cesarean section for vaginal bleeding at 36 weeks' gestation. The mother's pregnancy, labor and delivery were uncomplicated and the patient's Apgar scores were 9 and 9 at 1 and 10 minutes, respectively. The infant's postnatal course was uncomplicated until she was 3 days of age when hypertension was noted with a systolic blood pressure consistently greater than 110 mm Hg and ranging as high as 240 mm Hg. Renal arterial angiography when the infant was 3 months old showed an aneurysm of the left renal artery and a filling defect of the right renal artery (Fig. 1). Renin levels were elevated in both renal veins. Coronary angiography showed an aneurysm of the left coronary artery. Variable control of the hypertension was obtained with hydralazine alone or with chlorothiazide, and alpha methyldopa and chlorothiazide. At age 4 months, the infant died suddenly at home after her mother had failed for 3 days to administer all medications for hypertension.

Postmortem examination confirmed the left renal arterial aneurysm with thrombosis (Fig. 2) and showed a patent smaller adjacent channel with late stage arteritis changes compatible with mucocutaneous lymph node syndrome. Similar changes were seen in the small right renal artery, the coronary arteries, the aorta, the intrarenal arteries, the urinary bladder arteries and the mesenteric arteries.

Discussion

Clinical diagnosis: The diagnosis of the acute phase of mucocutaneous lymph node syndrome should be established relatively easily if it is fully developed with typical clinical features. Recognition may be a problem in the atypical or mild case because no pathognomonic laboratory features have yet been established.

The major pathologic changes of mucocutaneous lymph node syndrome are limited to the cardiovascular system, especially to the coronary arteries.[4,18,19] Electrocardiographic changes including prolongation of the P-R interval, prolongation of the Q-T interval and ST-T wave changes occur in more than 70 percent of the patients.[23] Approximately 20 percent of patients who survive have angiographic evidence of coronary arterial aneurysms or diffuse coronary arterial obstruction and 5 percent have mitral valve insufficiency.[20,21,24]

Recently, Japanese investigators[25] have proposed a "score-table" for determining the indication for invasive angiography. Their studies revealed that the following clinical features are associated with a large incidence of coronary arterial abnormalities, carditis and sudden death: (1) a male infant less than 1 year of age; (2) a prolonged or recrudescent fever for more than 16 days; (3) peripheral white blood cell count greater than 30,000/mm^3; and (4) erythrocyte sedimentation rate greater than 101 mm in 1 hour.

Noninvasive identification of the origins of the left and right coronary arteries by cross-sectional echocardiography[26] has enabled some investigators to diagnose proximal coronary arterial aneurysms in patients with mucocutaneous lymph node syndrome.[27,28] Because coronary arterial aneurysms occur in about 20 percent of the patients after the 2nd week of illness, serial cross-sectional echocardiograms may be useful in detecting the early development of aneurysms in the proximal coronary arteries in asymptomatic patients. However, the sensitivity of this method has not been established and, because an aneurysm may occur anywhere along the extramural coronary arteries, selective angiography is still indicated in convalescent patients. Serial angiographic studies may reveal regression of coronary arterial aneurysms.[20] The calcified lesion around the aortic root could be a diagnostic clue to the coronary arterial abnormalities, particularly in cases of long-term survival.

Prognosis: Tanaka et al.[18] found that the majority of deaths (53.7 percent) occurred among patients less than 2 years of age and 22.2 percent in patients less than

1 year of age. The peak time of death was 10 to 30 days after onset of the acute febrile illness with 20.3 percent of deaths occurring between 10 and 20 days and 37 percent between 20 and 30 days. In all of these cases there was marked to severe involvement of the coronary arteries.

Classification of cardiac lesions: On the basis of pathologic studies in 20 hearts of patients who had typical clinical signs and symptoms of the mucocutaneous lymph node syndrome, Fujiwara and Hamashima[19] classified the cardiac lesions of the syndrome from stage I to IV according to the duration of illness at death. *Stage I (0 to 9 days)* was characterized by acute perivasculitis and vasculitis of the microvessels and small arteries and by acute perivasculitis and endarteritis of the three major coronary arteries. Pericarditis, myocarditis, inflammation of the atrioventricular conduction system and endocarditis with valvulitis were

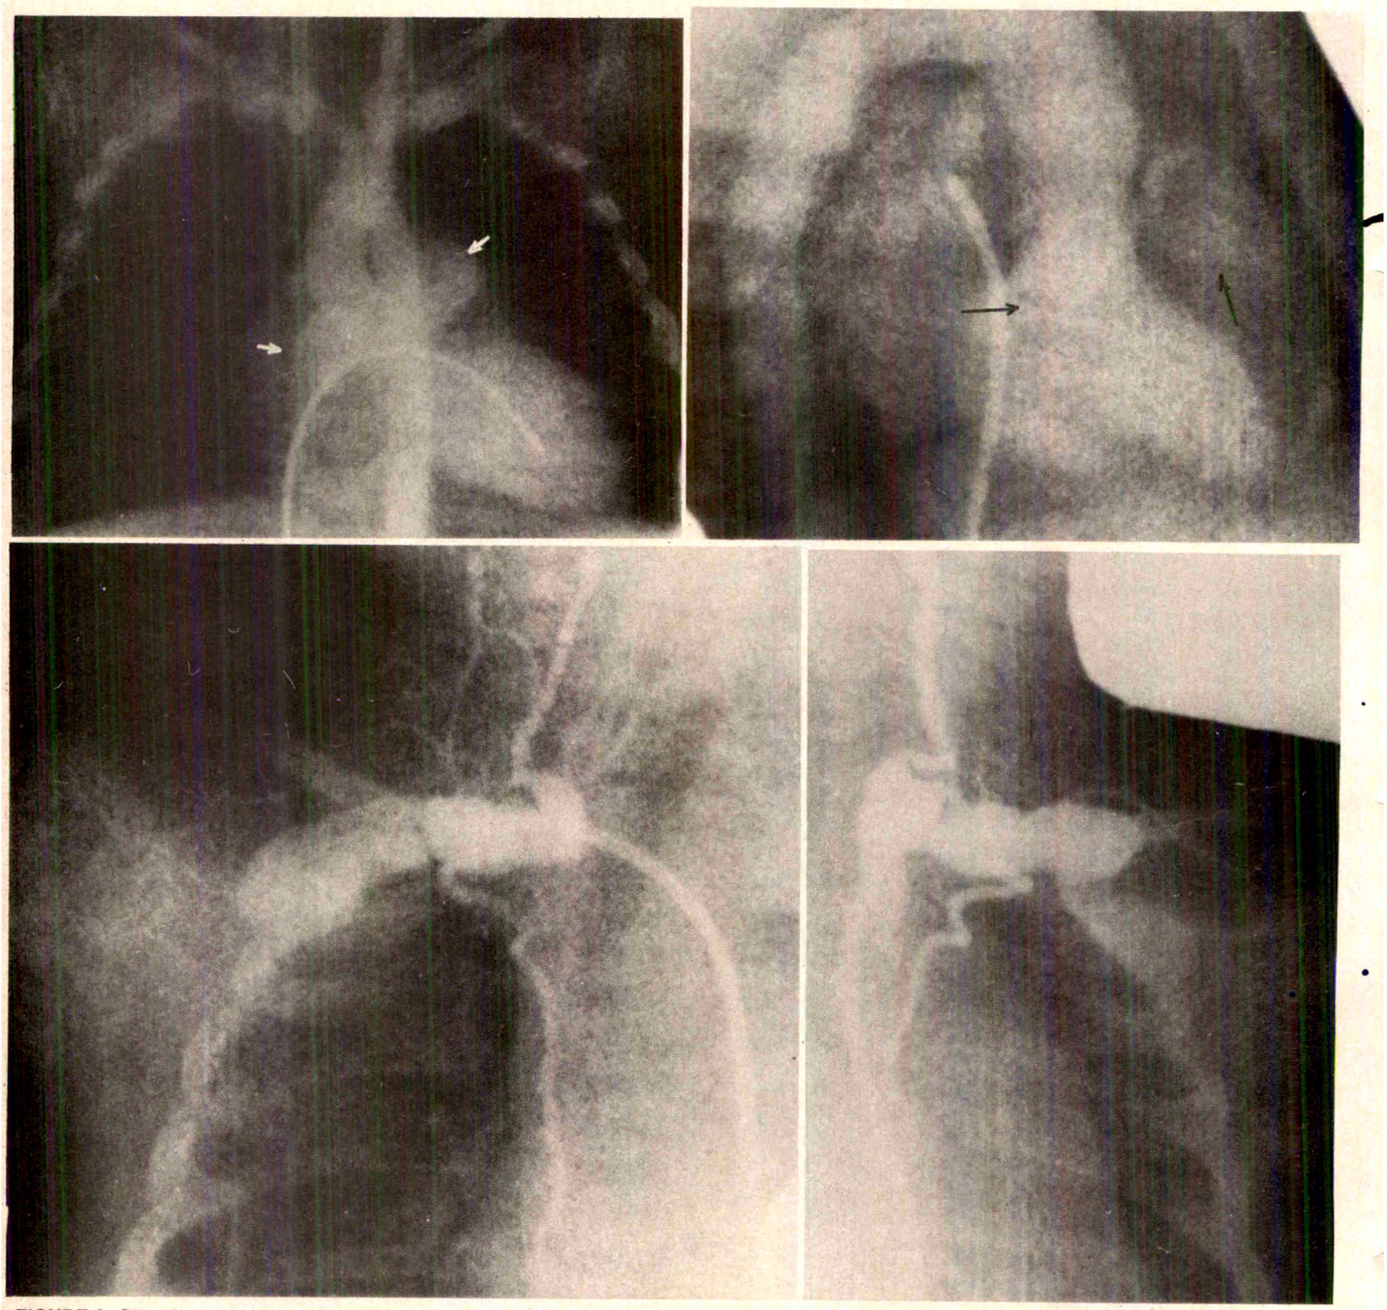

FIGURE 3. Case 2. Angiograms at age 3 months. **Upper left**, anteroposterior view of left ventricular injection and (**upper right**) lateral view of the left atrial injection showing large saccular aneurysms (**arrows**) of both right and left coronary arteries just distal to their origin. **Bottom left**, right and (**bottom right**) left subclavian arterial injections showing large tortuous, fusiform aneurysms of right and left distal subclavian arteries extending into both axillary arteries with complete distal obstruction of the right and decreased flow to the left brachial artery.

also present. *Stage II (12 to 25 days)* was characterized by panvasculitis of the coronary arteries and aneurysm with thrombus in the stems. Myocarditis, coagulation necrosis, lesions of the conduction system, pericarditis and endocarditis with valvulitis were also present. *In stage III (28 to 31 days)* granulation of the coronary arteries and disappearance of inflammation in the microvessels were noted. *In stage IV (40 days to 4 years)*, scarring with severe stenosis in the major coronary arteries was evident. Fibrosis of the myocardium, coagulation necrosis, lesions of the conduction system and endocardial fibroelastosis were also present. Fujiwara and Hamashima[19] concluded that the causes of sudden death in the mucocutaneous lymph node syndrome are myocarditis and inflammation of the conduction system in stage I, ischemic heart disease, rupture of aneurysm, myocarditis and lesions of the conduction system in stage II and ischemic heart disease in stages III and IV. The longest interval between clinical onset of the disease and death in their report was 4 years and 6 months.[19] In the United States, Munro-Faure[29] described a patient who died of myocardial infarction 5 months after the acute febrile illness; Tang and Segal[30] reported on a patient who died 5 months after onset.

In our series, Case 2 (Fig. 3 to 5) is an example of early sudden death (stage II) and Case 3 (Fig. 6) one of relatively early death with stage IV changes. Case 4 (Fig. 7) is an example of late sudden death from myocardial infarction with stage IV changes over an interval of 8 months after a febrile illness. Case 7 is a rare but well documented instance of long survival in a patient with a history of myocardial infarction 2 years and 3 months after the acute febrile illness. Case 8 (Fig. 1 and 2) is remarkable when the etiology of the mucocutaneous lymph node syndrome is considered. Because the child had hypertension as early as 3 days of age, presumably due to renal arterial lesions, the primary illness may have occurred in utero, although there was no history of any kind of viral type of illness during the pregnancy. Although this patient is a twin, her sibling has shown no evidence of the mucocutaneous lymph node syndrome or cardiovascular abnormality and is currently well. One might suspect that the same illness can be subclinical in adults and therefore might not be recognized. It has been reported[1] that the course of disease in older patients with the mucocutaneous lymph node syndrome is milder.

Coronary arterial aneurysm: Aneurysm of the coronary arteries without associated fistula is uncommon, and until recently it has rarely been diagnosed before death.[31,32] Previous reports have described cases of coronary arterial aneurysms of congenital origin[31,33–35] and in association with syphilis,[31] atherosclerosis,[31,32] septic embolus, periarteritis nodosa,[36] scleroderma,[37] Ehlers-Danlos syndrome[38] and bacterial infection.[39]

In 1963, Daoud et al.[32] compiled a total of 89 cases including their own 10 cases of coronary arterial aneu-

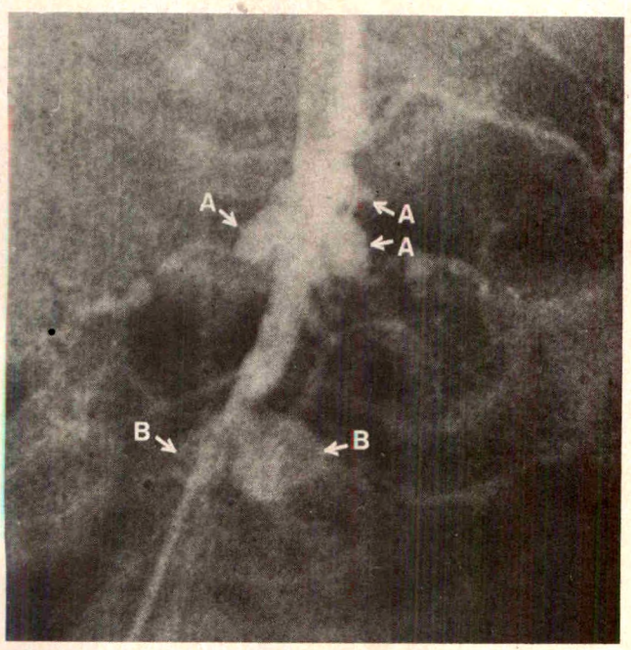

FIGURE 4. Case 2. Abdominal aortogram showing saccular aneurysms (A, **arrows**) at the origin of both renal arteries and the inferior mesenteric arteries. The common iliac arteries are obstructed distal to the bilateral aneurysms (B, **arrows**) at their origin.

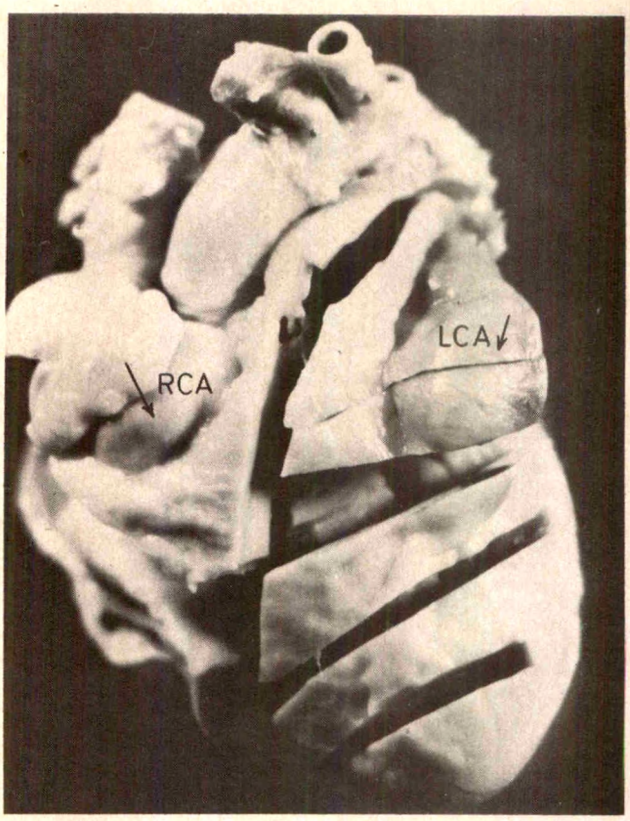

FIGURE 5. Case 2. Heart specimen showing large aneurysms (**arrows**) of the right (RCA) and left (LCA) coronary arteries. The patient died in the 5th week of illness from acute hemopericardium due to rupture of the aneurysm of the left coronary artery.

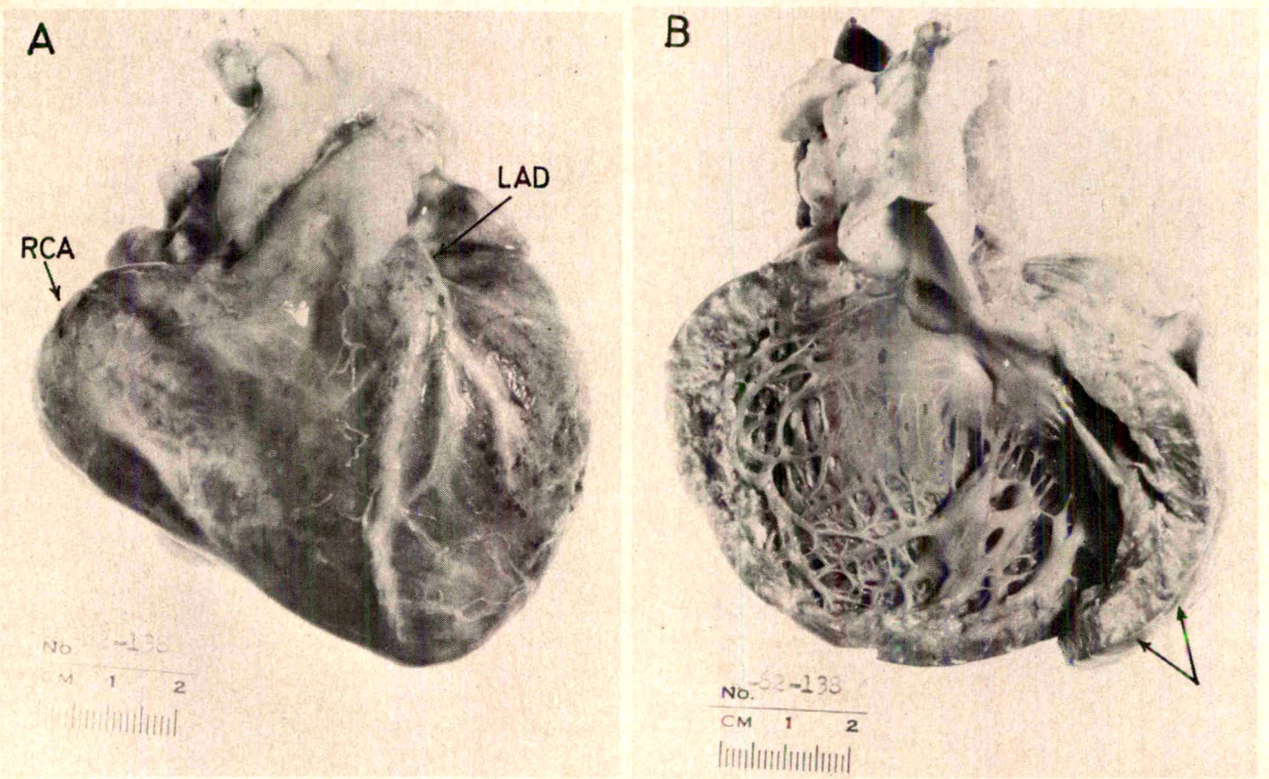

FIGURE 6. Case 3. Heart specimen at age 3 months. The patient died suddenly 3 months after a febrile illness. **A**, unusually prominent coronary arteries. The right main coronary artery has a diameter of 0.3 cm at its origin but the dilated segment extends to a diameter of 2.3 cm (RCA, **arrow**). The left anterior descending artery is also widely dilated at its origin with a diameter of 1.2 cm (LAD, **arrow**). Its distal branches are thickened. **B**, dilated left ventricle. Widespread fibrosis (**arrows**) is seen in the myocardium.

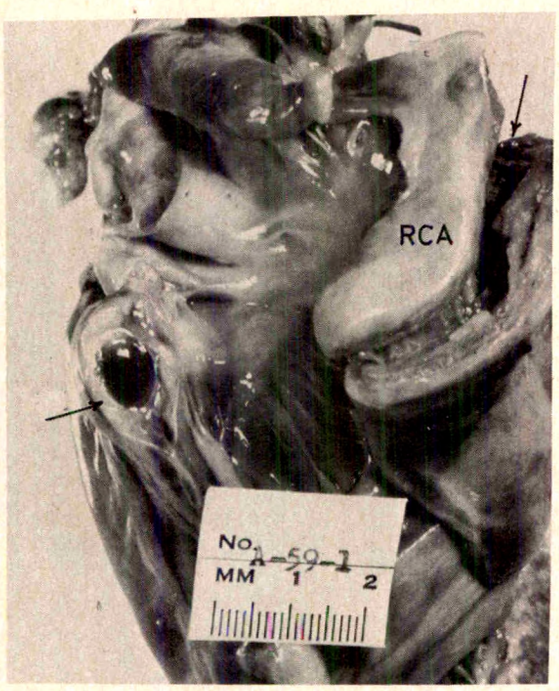

FIGURE 7. Case 4. Heart specimen at age 14 months. The patient died suddenly 8 months after a febrile illness. Focal aneurysmal dilatation of the right coronary artery (RCA, **arrows**) filled with thrombi of varying age can be seen along with marked thickening of the walls of the coronary arteries.

rysm diagnosed at postmortem examination. Forty-eight of 89 cases (52 percent) were considered arteriosclerotic and 16 (18 percent) congenital in origin. In 1975, Wilson et al.[34] compiled a total of 14 cases of coronary arterial aneurysm diagnosed during life. Two of these cases were considered to be arteriosclerotic and eight congenital; this suggests that arteriosclerotic aneurysms of the coronary arteries are more often incidental autopsy findings, whereas congenital aneurysms are more likely to produce symptoms thus direct clinical attention to the heart. Chest pain compatible with myocardial ischemia or infarction, or both, was reported in 10 of the 14 cases of this review.[34]

From recent reports and retrospective studies[4,19] it appears that infantile periarteritis nodosa and the mucocutaneous lymph node syndrome may be the same disease.[4,19] The clinical, pathologic and histologic findings in infantile periarteritis nodosa are identical to those of the mucocutaneous lymph node syndrome and are quite dissimilar to those of periarteritis nodosa of adult onset.[18,19] Tang and Segal,[30] reporting a case of sudden death 5 months after the onset of a febrile illness, pointed out that healed infantile periarteritis nodosa should be considered when one encounters multiple aneurysms of the coronary arteries in a young person; previously reported cases of "congenital aneurysms" certainly could have represented cases of healed infantile periarteritis nodosa with long survival. This

was also pointed out by Roberts and Fetterman,[40] who suggested that if the coronary arterial lesions are all in the reparative stage (stage IV in the classification of Fujiwara and Hamashima), one might hesitate to make the diagnosis of infantile periarteritis nodosa.

In two of our patients with coronary aneurysms (Cases 6 and 7) chest pain developed approximately 2 years after the febrile illness (in Case 7 after an apparent episode of myocardial infarction). Patient 6 (Fig. 8) required surgical intervention but Patient 7, now 18 years of age, is currently asymptomatic, although clinical findings such as those from the chest roentgenogram, electrocardiogram and echocardiogram are clearly abnormal. Case 7 could well be diagnosed as "congenital aneurysm" of the coronary artery unless one obtained the previous history of mucocutaneous lymph node syndrome. It seems that healed mucocutaneous lymph node syndrome or infantile periarteritis nodosa has become one of the most likely alternative diseases in the differential diagnosis of coronary arterial aneurysms in children or even in adults.

Systemic arterial aneurysms: Such aneurysms have been described in association with Takayasu's disease,[41] atherosclerosis, trauma, syphilis and Marfan's

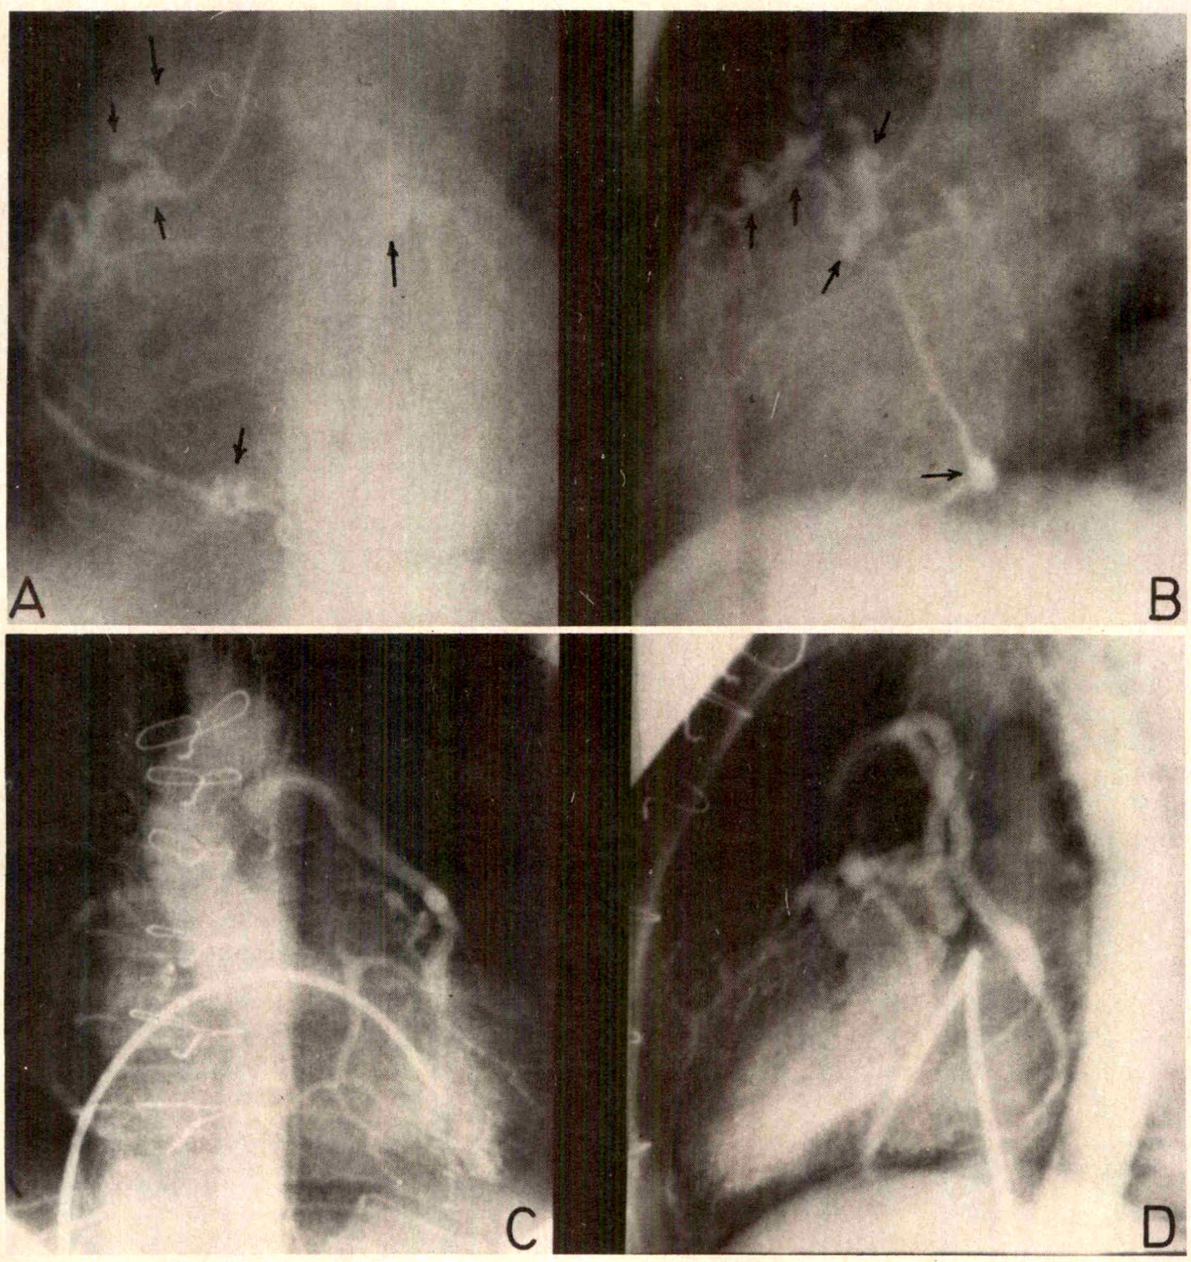

FIGURE 8. Case 6. Pre- and postoperative angiograms at 7 years. **A** and **B**, selective right coronary arteriogram in left anterior oblique (**A**) and lateral (**B**) projections showing multiple coronary arterial aneurysms (**arrows**) of both the right and the left coronary arteries. There is evidence of retrograde filling of the left coronary artery, which is completely obstructed at its origin. **C** and **D**, postoperative left ventricular angiogram in anteroposterior (**C**) and lateral (**D**) projections showing patency of three vein grafts that fill the distal branches of the coronary arteries.

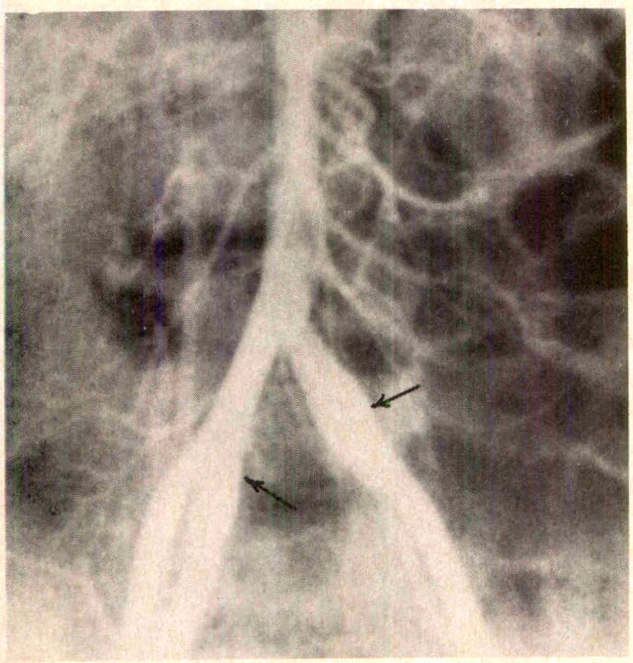

FIGURE 9. Case 5. Abdominal aortogram at age 3 1/2 years showing small bilateral fusiform iliac arterial aneurysms (**arrows**).

syndrome. Tanaka et al.[18] has described iliac, testicular, mesenteric, renal and pancreatic arteries as other sites of arterial involvement with mucocutaneous lymph node syndrome. Another autopsy report of 20 patients with mucocutaneous lymph node syndrome from Japan,[19] 14 of whom died suddenly, described a 6 month old male infant whose death was caused by rupture of an aneurysm of the femoral artery during the acute phase of the disease. In contrast, late formation of aneurysms of brachial, iliac, cervical and other large arteries has been described in patients with the mucocutaneous lymph node syndrome.[21] Our Case 5 (Fig. 9) is a good example of late aneurysm formation.

Asymptomatic patients who present with peripheral arterial aneurysms may have aneurysms of the main branches of the aorta, most importantly the coronary and renal arteries. For this reason, in such patients with peripheral arterial aneurysms, we recommend further investigation, including angiography, even when there has been no typical history of the mucocutaneous lymph node syndrome because "formes frustes" of this disease could easily be diagnosed as viral syndrome.

Treatment: Patients in the acute phase of the disease have been treated with corticosteroids and anticoagulants, but it is not clear whether this mode of treatment will prevent further complications from coronary arterial involvement.[1,17] Aspirin, with its antiinflammatory, antipyretic and antithrombotic properties, seems to be a reasonable choice of treatment. Thrombocytosis and increased aggregation of platelets have been well recognized in this syndrome.[1,42] More extensive anticoagulant treatment with heparin or coumarin may be indicated in patients with evidence of occlusive vascular disease, especially in the limbs.[21] The mucocutaneous lymph node syndrome has been treated with various antibiotic agents, including penicillin and chloramphenicol, without clear evidence of remission.[1] A Rickettsia or Rickettsia-like organism has been reported as a possible pathogenic agent.[12,43]

Surgical treatment for coronary arterial obstructive lesions as sequelae of the mucocutaneous lymph node syndrome was first performed successfully in 1974 on a 5 year old boy in whom myocardial infarction developed.[25] Since then, to our knowledge, 10 surgical cases with satisfactory results have been reported from Japan.[25,27,44]

Further long-term follow-up studies of the patients who have survived the acute stage of the mucocutaneous lymph node syndrome are necessary to establish the spectrum of late complications and sequelae as well as to determine the accurate diagnosis and proper management of the patient during the acute stage.

Acknowledgment

We thank Frank Sandiford, MD for permission to publish data on his patient (Case 6).

The Surgical Decision in Tetralogy of Fallot: Weighing Risks and Benefits With Decision Analysis

ARTHUR GARSON, Jr., MD

DENTON A. COOLEY, MD, FACC

Houston, Texas

The preferred management of the symptomatic infant less than 2 years of age with tetralogy of Fallot remains unsettled. In this study decision analysis was used to assess the risks and benefits of three courses of action: (1) primary intracardiac repair; (2) palliative operation in infancy and delayed intracardiac repair; and (3) treatment with propranolol in infancy and delayed intracardiac repair. For each action the likelihood was determined of three possible outcomes for the patient: (1) death, (2) poor surgical result, or (3) good surgical result. Each outcome was associated with an estimated life expectancy. The best action was defined as that resulting in the longest life expectancy. With use of previously reported data and those from experience at one institution, a range of probabilities was estimated for death before operation, surgical mortality, success of propranolol treatment and hemodynamic result of operation. The choice of action was affected most by the mortality of primary intracardiac repair and the likelihood of a good hemodynamic result from intracardiac repair. Less important factors were the outcome of a palliative operation and the likelihood of success with propranolol therapy. It was found that in the institution studied if the mortality rate of primary intracardiac repair is 10 percent or less, intracardiac repair should be performed; otherwise propranolol treatment, which allows delay in intracardiac repair, should be selected. Both alternatives are preferable to palliative operation. With decision analysis, the clinician can use probabilities and life expectancy appropriate to a given clinical setting in determining the best management for the infant with tetralogy of Fallot.

Recently, different opinions have been cited regarding the ideal medical and surgical management of infants with tetralogy of Fallot. Some investigators[1,2] have recommended primary intracardiac repair in young infants, whereas others[3,4] continue to use "staged" management consisting of aorticopulmonary anastomosis followed later by intracardiac repair. Some[5] have reported success using treatment with propranolol to relieve hypoxemic spells and delay intracardiac repair.

Each physician presented with an infant having hypoxemic spells due to tetralogy of Fallot must consider not only the immediate mortality of the various alternative modes of therapy, but also their long-term consequences. Questions must be asked such as: What is the risk of primary intracardiac repair in this infant? What is the likelihood that propranolol will eliminate spells? If the drug does eliminate the spells, how long will its beneficial effect last, and what are the possible complications associated with the therapy? What is the advantage of early elimination of right to left shunting? How long will the infant live if a poor hemodynamic result is obtained from intracardiac repair? Other factors weigh importantly in this decision, but these questions are sufficient to indicate the complexity of the choices.

We have analyzed the management decision in tetralogy of Fallot using an approach known as *decision analysis.* Decision analysis embodies a formal method for representing problems in which uncertainties and risk play important roles.[6–8] One of the potential benefits of decision analysis in the management of tetralogy of Fallot is that it provides a logical framework within which differences of opinion among clinicians can be integrated.

Background

Decision analysis: This embodies a formal theory of making decisions in the face of uncertainty. The methods of decision analysis are technical, having solid grounding in mathematics, but the appreciation and application of these methods do not require an extensive mathematical background. Decision analysis is most useful in situations in which clear definitions of the options available to the decision maker can be made. The theory prescribes the following general procedure for making a decision such as that facing the clinician in the management of tetralogy of Fallot[9]: (1) List the options that are actually available for consideration. (2) Carefully describe the consequences that may possibly follow each option. (3) Arrange these options and consequences, including subsequent options, in chronologic order, and assign to each consequence a value. (4) Assess in quantitative terms the chance that each consequence will occur. At this point, the problem can be represented in a *decision tree,* such as that shown in Figure 1 for an infant with tetralogy of Fallot.

Decision tree: A decision tree consists of nodes and branches. There are two kinds of nodes. At a *decision node* (square in Fig. 1) the clinician is required to choose one of a set of actions, in this case intracardiac repair, aorticopulmonary anastomosis or administration of propranolol. At *chance nodes* (circles in Fig. 1) the consequences of actions are represented. Thus, for example, assume that at the decision node in Figure 1 the clinician chooses intracardiac repair. The branch corresponding to that action leads to the chance node labeled intracardiac repair (ICR). The consequences of the action are then characterized as either a "good" or a "bad" result when the assessment is made at postoperative cardiac catheterization. (These terms will be defined subsequently.) The chance node is associated with probabilities that represent the chances that the respective outcomes will occur.

The value of a given choice represents the relative desirability of the consequences. Thus, the outcome in tetralogy of Fallot can be assessed in terms of different values such as patient's survival, functional status or life expectancy. A detailed discussion of subjective assessment of values is available elsewhere.[6–8] Recently, several examples of the use of these techniques in the clinical setting have been presented.[7,10]

Life expectancy to gauge value of outcome: Virtually all patients who survive intracardiac repair are asymptomatic[9]; thus, one can assume that the quality of their lives is good. Hence, it seems reasonable to approximate the value of such an outcome by life expectancy, because the quality of life is unchanged and only the longevity may differ from that of the general population. This is in contrast to the situation with surgery for coronary artery disease, in which patients may still be symptomatic after operation. In these patients, the value of an outcome must be assessed not only by early mortality but also by the expectation of chest pain and the limitation of activity after operation.[7]

Decision analysis provides a way of combining the values of an outcome with the probabilities of achieving the outcome to obtain an overall assessment of the relative merits of the choices being considered. Choices are ranked in terms of the expected value of the implied consequences. In our example, the *expected value* of a choice would be measured by the expected lifetime of the infant. For example, the choice of intracardiac repair can ultimately lead to a set of outcomes, each of which is associated with a different life expectancy. When life expectancy for each outcome is weighted by the probability that each corresponding outcome will occur, the result is the overall life expectancy for intracardiac repair.

Application to Tetralogy of Fallot

We will begin the analysis with the presentation of a typical case. The same procedure can be used for any patient with tetralogy of Fallot.

Case 1: A 6 month old child was being followed up primarily by the cardiologist in our group who had been studying propranolol. This child had been mildly cyanotic since 6 weeks

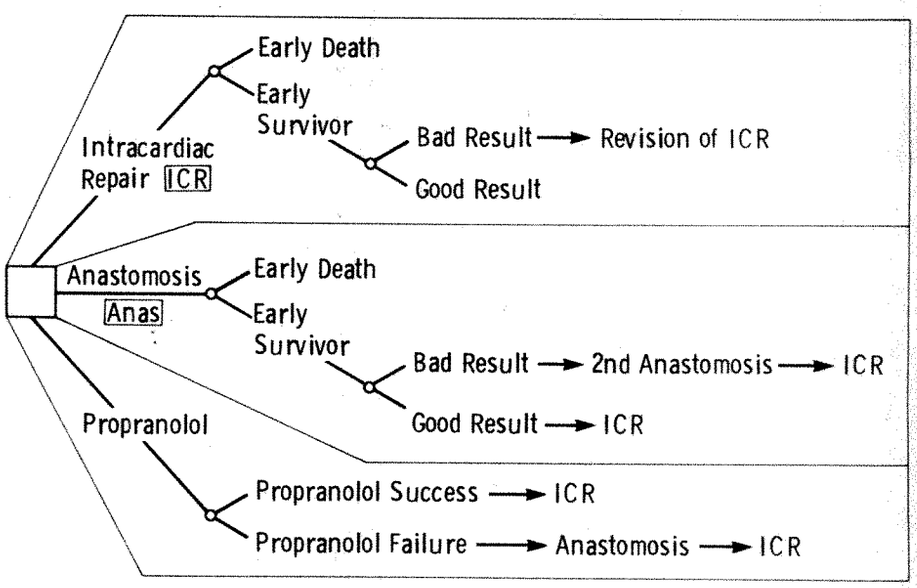

FIGURE 1. Decision tree for the management decision in an infant with tetralogy of Fallot. At the **square node** the physician must make a choice. Either primary intracardiac repair (ICR), anastomosis, (Anas), or propranolol therapy will be chosen. If the choice is primary intracardiac repair, the first branch point in the tree is a round node, a "chance node". This node, early survival from intracardiac repair, is controlled by probability, as are all the rest of the nodes in the tree. If a patient survives repair, he will have either a good or a poor hemodynamic result. The tree is followed in this manner. **Arrows** indicate that several steps are omitted.

of age but presented at age 6 months (weighing 4.5 kg) with the recent onset of hypoxemic spells. Three cardiologists who saw the child agreed that intervention was necessary; however, each recommended a different type of treatment.

We shall now analyze the decision quantitatively. This analysis will attempt to determine which factors in the decision contribute most to the final choice and, given those factors for this patient, what the best choice is.

The Decision Tree

The three choices—perform primary intracardiac repair, perform aorticopulmonary anastomosis or administer propranolol—are shown in Figure 1. If the patient survives anastomosis or propranolol therapy, these choices are assumed to lead eventually to intracardiac repair. All patients who have intracardiac repair are assumed to face the same outcomes after intracardiac repair regardless of whether an anastomosis or administration of propranolol preceded the intracardiac repair. Therefore, the structure of the decision tree will be the same for all patients after intracardiac repair, with different probabilities of the outcomes assigned depending on circumstances.

Primary intracardiac repair (Fig. 2A): If primary intracardiac repair is chosen, the patient's subsequent course follows the corresponding decision branch and arrives immediately at the first chance node labeled "intracardiac repair." What happens here is determined by the probability of early death (within 30 days) as a result of primary intracardiac repair in a 6 month old child. If the patient survives 30 days, we shall assume that he lives at least long enough to undergo postoperative cardiac catheterization. The hemodynamic result determined at cardiac catheterization might be either "good" or "bad." A bad result is defined as the presence of a ventricular septal defect with a pulmonary to systemic flow ratio equal to or greater than 1.5:1, right ventricular peak systolic pressure equal to or greater than 60 mm Hg or distal pulmonary arterial peak systolic pressure equal to or greater than 40 mm Hg. Other results will be termed

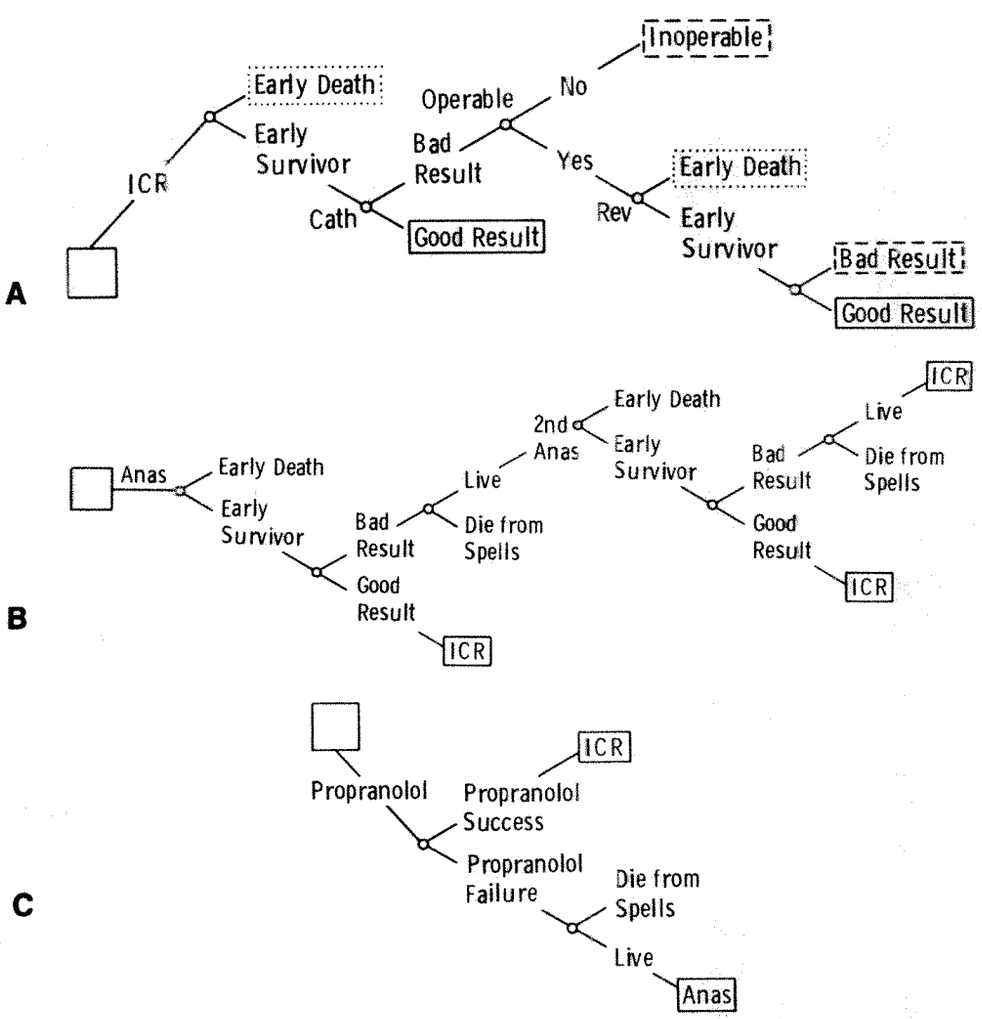

FIGURE 2. Decision trees. **A,** complete tree for primary intracardiac repair (ICR). The **square node** indicates that this is only one of the three choices outlined in Figure 1. **Middle,** for aorticopulmonary anastomosis (Anas). The **boxes** labeled ICR indicate that these patients have intracardiac repair at that point. In actual use, the entire decision tree in **A** replaces each ICR box. **C,** for propranolol therapy. In patients who live after failure of propranolol therapy, anastomosis is performed. In actual use, the box for anastomosis is replaced by the entire decision tree in **B**, and the ICR box by the decision tree in **A.** Cath = catheterization; Rev = revision operation.

"good."[9] If the patient has a good result, it is a "final outcome," that is, one not followed by additional surgery. However, if he or she has a bad result, this result can be either "inoperable" or "operable." The patient who is unable to undergo a "revision" operation, that is, one who is judged "inoperable after primary ICR" has either (1) pulmonary vascular obstructive disease, (2) surgically inaccessible pulmonary branch stenosis, or (3) right or left ventricular failure resulting from reduced myocardial contractility. Such a patient has arrived at a final outcome. We shall assume that all patients who are "operable" have surgery to revise the intracardiac repair. Again, if a patient survives the revision operation he can have either a good or bad hemodynamic result. Because we assume that a patient has only one revision operation, the outcomes ("good result" and "bad result") are the final outcomes. *We therefore assume that there are only four possible final outcomes for a patient who has primary intracardiac repair.* The patient then (1) dies within the first 30 days after an operation; (2) survives at least 30 days and has a bad hemodynamic result with a resulting inoperable condition; (3) survives reoperation with a bad hemodynamic result; or (4) survives either primary intracardiac repair or reoperation with a good hemodynamic result.

Aorticopulmonary anastomosis (Fig. 2B): If a patient has an aorticopulmonary anastomosis, the first chance node denotes whether the patient will survive 30 days after anastomosis. In our institution a 4.5 kg child would most likely have an ascending aorta to right pulmonary artery anastomosis. If the child survives, he would have either a good or a bad result. A good result of anastomosis is here defined as the absence of hypoxemic spells for at least 12 months, thereby allowing intracardiac repair to be postponed until the patient weighs 9 kg. We assume that all patients who have a good result have intracardiac repair at the weight of 9 kg. The decision "path" in such a patient would then follow the same branches as that of a patient who had primary intracardiac repair, but with different probabilities of outcome. A bad result after the first anastomosis is defined as a result of hypoxemic spells within less than 12 months. If the spells return, a delay of 1 month is assumed between the parents' recognition of the first spell and another palliative operation. During this time, the patient may die from a hypoxemic spell. If he survives, he will undergo a second palliative procedure. In our institution, he would have either a revision of the ascending anastomosis or a subclavian to pulmonary artery (Blalock-Taussig) anastomosis. The options discussed earlier are then faced again. If the child survives the second operation and has a good result, he later has intracardiac repair at a weight of 9 kg or more. If he has a bad result from the second anastomosis, we assume that immediate intracardiac repair will be performed.

Thus a patient who has an anastomosis could have one of six final outcomes: early death after a palliative operation; death from a hypoxemic spell while awaiting either a second palliative operation or intracardiac repair; and the same four final outcomes as for patients who had primary intracardiac repair. Although the outcomes are the same, the probabilities of the outcomes may differ. For example, a prior ascending aorta to right pulmonary artery anastomosis may distort the right pulmonary artery and thus decrease the probability of an eventual good hemodynamic result from repair.

Propranolol (Fig. 2C): If the decision is made to administer propranolol and the treatment is successful (defined as the absence of hypoxemic spells for at least 12 months), the patient will have intracardiac repair at a weight of 9 kg or more. If drug therapy is unsuccessful, spells either persist or return within 12 months. In either case, a delay of at least 2 months is assumed before the drug treatment is labeled unsuccessful. During this time, the patient may die from spells,

TABLE I

Probabilities of Events

Events	Probabilities		
	Probability Range From Previous Reports	Reference	Probability Estimate in 6 Month Old Infant (TCH)
Primary ICR			
Early death	0.05–0.20	1, 2	0.20
Poor hemodynamic result	0.06–0.25	11, 12	0.25
Inoperable after primary ICR	0.20–0.50	11, 12	0.25
Early death after reoperation	0.07–0.50	12, 13	0.15
Poor hemodynamic result	0.25–0.36	11, 14	0.30
Primary aorticopulmonary anastomosis			
Early death (first or second anastomosis)	0.05–0.09	12, 15, 16	0.05
Poor hemodynamic result (first or second anastomosis)	0.01–0.05	12, 16	0.05
Early death after ICR (after successful anastomosis)*	0.05–0.20	1, 2, 9	0.12
Inoperable after ICR	0.20–0.50	9, 11	0.25
Death from hypoxemic spells	0.01–0.04	17–19	0.01
Propranolol therapy			
Propranolol success	0.45–0.70	5	0.60
Early death after ICR	0.05–0.15	1, 5	0.12
Poor result after ICR	0.10–0.32	9, 13	0.25
Death from spells	0.01–0.04	17–19	0.01

* Probabilities after poor hemodynamic result from second anastomosis are not listed because fewer than 1 percent of patients will have this outcome.

ICR = intracardiac repair; TCH = Texas Children's Hospital.

with increasing infundibular stenosis. If the drug treatment is unsuccessful and he survives, he will then have an anastomosis and follow the same decision tree outlined in Figure 2B, but with different probabilities.

The patient who receives propranolol also would have one of six possible final outcomes. One outcome is death from hypoxemic spells before either type of surgical procedure can be carried out. The other five possible final outcomes are the same as those of the other two decision trees because all patients who receive propranolol presumably will eventually require either an anastomosis or intracardiac repair.

Probability Assessment

Table I contains the probabilities for each of the events in Figure 2. In column 2 are the reported ranges for the probabilities for patients of all ages with tetralogy of Fallot. In column 4 are the probabilities we have assumed for a patient at Texas Children's Hospital similar to the one presented as Case 1 (a 6 month old, 4.5 kg child). The final outcomes that a patient can have in each part of the decision tree are, as mentioned, (1) early death (from hypoxemic spells or operation); (2) poor hemodynamic result (whether the patient is "inoperable" after the first intracardiac repair or has a bad result after revision); and (3) a good hemodynamic result (whether from intracardiac repair or revision). The probability of occurrence of any final outcome at the end of a series of events is calculated by multiplying together each of the probabilities in the series. For example, in the choice for primary intracardiac repair in a 6 month old infant (Fig. 3), the probability of a good result from the first intracardiac repair (0.60) is found by multiplying the probability of being an early survivor (0.80) by the probability of a good result, *given* that the patient was an early survivor (0.75). This probability of a good result equals 0.60. Another way of stating this probability is that 75 percent of patients who survive the first intracardiac repair (80 percent of total) will have a good result. Patients can also have a final good result after revision; thus, the total probability of a good result is 0.60 + 0.09 = 0.69. If the probabilities of all final outcomes for a single choice are added together, the sum equals 1.0. Thus, in Figure 3, 0.69 + 0.09 + 0.22 = 1.0.

These probabilities can help in the evaluation of the choice of therapy. The choice with the highest probability of a good result, as well as the lowest probability of either a poor result or death, would be the most preferred. For a 6 month old patient at Texas Children's Hospital, the probabilities of the final outcome are listed in Table II. The best choice is treatment with propranolol because it has a higher probability of a good result and a lower probability of death than either anastomosis or primary intracardiac repair. Whereas simple probability analysis is valuable in this particular case, in instances where the probabilities of all three final outcomes are changing, it is helpful to have a number that denotes the worth or "expected value" of a choice. We now consider the assessment of that worth.

Evaluating Final Outcomes

Because the vast majority of patients are asymptomatic after repair of tetralogy of Fallot, the quality of life is assumed to be the same in patients regardless of the hemodynamic result. Therefore, length of survival was chosen as the measure of the value of final outcomes for these patients. A recent long-term study[12] of patients with tetralogy of Fallot indicates that patients with a good hemodynamic result from intracardiac repair of tetralogy of Fallot die at a rate of approximately 1 percent a year. Let us assume that these patients will follow the life table for normal persons in the United States. The expected lifetime for a normal 6 month old infant in the United States is 71 years.[20] In contrast, patients with a poor hemodynamic result after intracardiac repair of tetralogy of Fallot die at a rate of approximately 3 percent a year.[12] If we assume that each year 3 percent of the remaining patients will die, an exponential function describes the survival curve and the calculated expected lifetime is 33.3 years. For death either during or soon after surgery, the expected lifetime is, of course, 0 (Fig. 4).

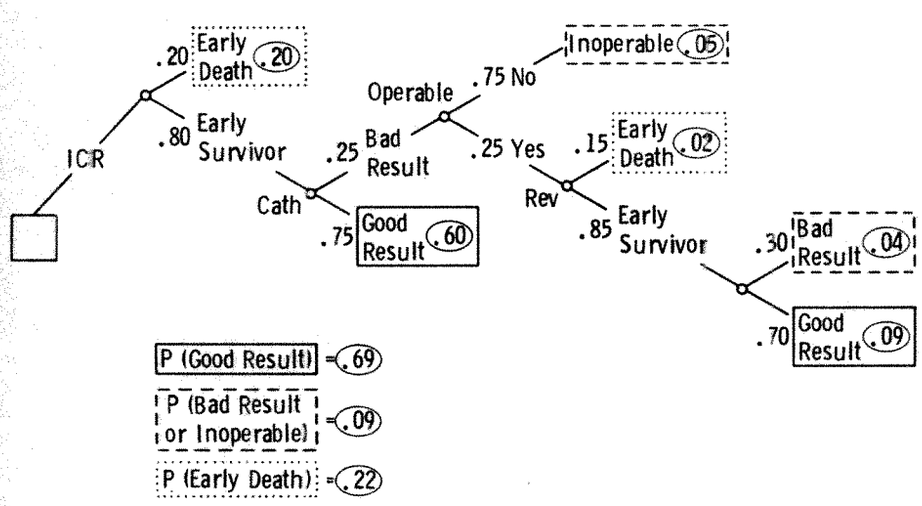

FIGURE 3. Decision for the choice of primary intracardiac repair (ICR) in a 6 month old child at Texas Children's Hospital. Probabilities for each outcome of an event are given with each branch of the tree. The probability of surviving intracardiac repair equals 0.80 and the probability of early death equals 0.20. The probabilities for achieving a particular final outcome are shown in **circles** (for example, the probability of a good result from the first intracardiac repair equals 0.60). The probabilities (P) of arriving at each of the three final outcomes are listed **at bottom.**

TABLE II

Probabilities of Final Outcomes (6 month old infant at Texas Children's Hospital)

Probability of Final Outcomes	Therapeutic Choices		
	Primary Intracardiac Repair	Aorticopulmonary Anastomosis	Propranolol
Good result	0.69	0.70	0.76
Poor result	0.09	0.09	0.09
Death	0.22	0.21	0.15

Expected Value

Each of the three choices in the decision (intracardiac repair, anastomosis, treatment with propranolol) has in turn three possible final outcomes (good result, poor result, early death). To obtain the expected value for a particular final outcome, the probability of each final outcome is multiplied by the expected lifetime of the patient with this outcome. In Table III, a sample calculation for a 6 month old child at Texas Children's Hospital is illustrated. For primary intracardiac repair, the probability of a good result is 0.69. The expected lifetime for any patient with a good result is 71 years. The expected value of a good result is 49 years (0.69 × 0.71). To obtain the expected value for the entire choice, the expected values for each final outcome are added together. For primary intracardiac repair, the total expected value is 52 years (49 + 3 + 0). If the same group had anastomosis and later intracardiac repair instead, its expected lifetime would be 57 years. Therefore, for such an infant, primary intracardiac repair and anastomosis appear to have about the same relative value, but each is less preferable than initial therapy with propranolol followed later by intracardiac repair.

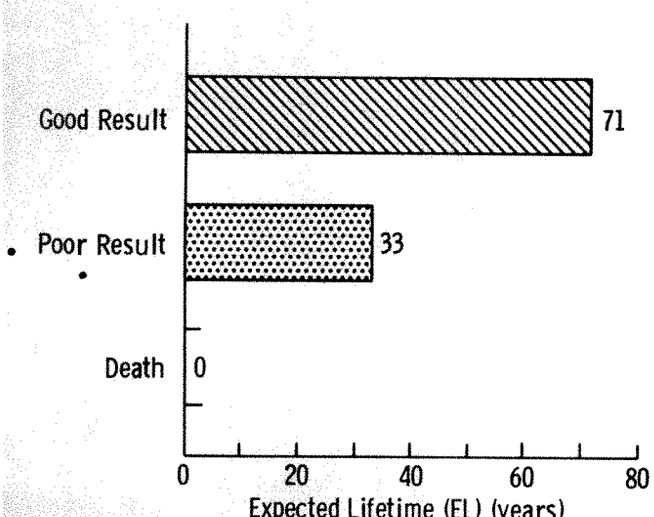

FIGURE 4. Estimated lifetimes for a 6 month old infant with tetralogy of Fallot. Patients with a good result are assumed to follow the United States life table with an expected lifetime of 71 years. Patients with a poor result are assumed to die at a rate of 3 percent a year, with an expected lifetime of 33 years. Patients who die early after intracardiac repair have an expected lifetime of zero.

TABLE III

Calculation of Expected Values* (6 month old infant at Texas Children's Hospital)

	Therapeutic Choices		
	Primary Intracardiac Repair	Aorticopulmonary Anastomosis	Propranolol Therapy
Probability of final outcome			
Good result $P_{(GR)}$	0.69	0.70	0.76
Poor result $P_{(PR)}$	0.09	0.09	0.09
Death $P_{(D)}$	0.22	0.21	0.15
Utilities (U)			
Good result	71 years	71 years	71 years
Poor result	33 years	33 years	33 years
Death	0	0	0
Expected values			
Good result	49.0 years	49.7 years	54.0 years
Poor result	3.0 years	3.0 years	3.0 years
Death	0	0	0
Total expected values	52.0	52.7	57.0

* Expected values of therapeutic choice = $[P_{(GR)} \times U_{(GR)}] + [P_{(PR)} \times U_{(PR)}] + [P_{(D)} \times U_{(D)}]$.

These conclusions are based on assumed probabilities and assumed expected lifetimes. The range of probabilities found in publications[11,13–19] (Table I) indicates that other institutions would use different numbers. The example cited here simply illustrates how the calculations are made. The same procedure may be

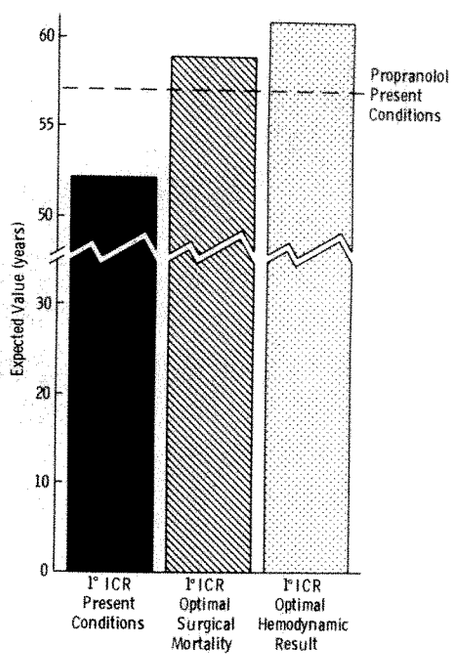

FIGURE 5. Comparisons of expected values with propranolol therapy and primary intracardiac repair (1° ICR) when different probabilities of events are assumed. Under present conditions at this institution for a 6 month old infant, the expected value of propranolol therapy (**dotted line**) is higher than that of primary intracardiac repair. If the best possible surgical mortality or the best possible hemodynamic results are assumed, then the expected value for primary intracardiac repair is higher than that for propranolol therapy.

used by any institution in evaluating management choices in patients of all ages.

Sensitivity Analysis

Range of expected values for choices based on probabilities for the events: Through sensitivity analysis one can determine how much certain events influence the decision. By substituting the range of probabilities for a single event, one can recalculate the probabilities for the three final outcomes and the overall expected values of the choices. If, by changing the probabilities of a certain event, the overall expected value of a choice changes appreciably, the decision is said to be *sensitive* to changes in the probability for that event. For example, the range of probabilities for early death after primary intracardiac repair is 0.05 to 0.20 (Table I). If 0.05 instead of 0.20 is inserted at the first chance node in Figure 3, the final outcome probabilities would be: probability of a good result = 0.81; probability of a poor result = 0.11; probability of early death = 0.08. The expected values for the outcomes would be 57.5, 3.6 and 0 years, respectively. The expected value for intracardiac repair is 61.1 (57.5 + 3.6 + 0). This is higher than 52.0 years, the expected value for intracardiac repair with probability of early death = 0.20 (Table III). Table IV lists the range of expected values for the choice obtained when the probabilities for the events are varied from the lowest value (best result) to the highest value (worst result) found in published results. The value for the difference between the lowest and highest value determines the sensitivity; the more the expected values change, the more sensitive the decision is to this event.

Mortality and hemodynamic result: the most sensitive probabilities: For all three choices, the expected values are most sensitive to the probability of early death from intracardiac repair, the probability of a poor hemodynamic result after intracardiac repair and the probability of early death after revision. The expected values are less sensitive to the mortality and results of anastomosis and to the likelihood of success with propranolol therapy. The expected values are virtually insensitive to the probability of death from hypoxemic spells.

Table IV and Figure 5 show that if the mortality of primary intracardiac repair in the infant were lowered to 0.05, primary intracardiac repair would be the preferred choice (expected lifetime = 61.1 years). Similarly, if the probability of a poor hemodynamic result were lowered to 0.06, the expected lifetime would be 58.9 years, and again primary extracardiac repair would be preferred over treatment with propranolol (Fig. 5). If the probability of early death from primary intracardiac repair is equal to 0.11 or the probability of a poor hemodynamic result from primary intracardiac repair is equal to 0.14, the expected lifetime with propranolol therapy is equal to that with primary intracardiac repair. Therefore, if the probability of early death from primary intracardiac repair is 10 percent or less *or* the probability of a poor hemodynamic result from primary intracardiac repair is 13 percent or less (with other probabilities unchanged), then primary intracardiac repair would be the choice at our hospital.

Discussion

The results of this analysis have shown that decision analysis can be of use in clarifying the problem of the management of the symptomatic infant with tetralogy of Fallot. When the three alternative therapeutic choices are depicted in a decision tree, the possible fates of an individual patient are readily apparent. This step alone has been useful in both graduate and postgraduate

TABLE IV

Sensitivity Analysis of Events in Tetralogy of Fallot

Event	Best Result		Worst Result		Range of Expected Values*
	Probability	Expected Value	Probability	Expected Value	
Primary ICR					
Early death	0.05	61.1	0.20	52.0	9.1
Poor hemodynamic result	0.06	58.9	0.25	55.1	3.8
Inoperable after primary ICR	0.20	55.2	0.50	54.0	1.2
Early death after reoperation	0.07	55.8	0.50	52.0	3.8
Poor hemodynamic result after reoperation	0.25	55.5	0.36	54.8	0.7
Anastomosis					
Early death	0.05	54.1	0.09	52.0	2.1
Poor hemodynamic result	0.01	53.4	0.05	52.7	0.7
Early death after ICR	0.05	56.9	0.20	48.1	8.8
Poor hemodynamic result after ICR	0.10	55.3	0.39	50.1	5.2
Inoperable after ICR	0.20	52.3	0.50	51.5	0.8
Death from spells	0.01	52.7	0.04	52.7	0
Propranolol					
Propranolol success	0.40	58.4	0.70	55.1	3.3
Early death after ICR	0.05	58.0	0.15	54.5	3.5
Poor result after ICR	0.10	60.3	0.32	56.0	4.3
Death from spells	0.01	57.3	0.04	56.0	1.3

* This column was obtained by subtracting the expected value of the worst result from the expected value of the best result.
ICR = intracardiac repair.

medical education programs teaching medical students and residents the possible outcomes for a given disease.[21]

Sensitivity analysis demonstrated which events would affect the decision and which would not. It is not surprising that the decision is quite sensitive to mortality and to hemodynamic results of intracardiac repair. The decision is less sensitive to the mortality and hemodynamic results of anastomosis. This is because death and poor results of anastomosis are such unlikely events that small changes in their probabilities do not affect the overall decision. The same appears to be true for the probability of death from hypoxemic spells. Death is an uncommon event if not more than 2 to 3 months elapse, with the patient having spells associated with failure of either propranolol therapy or anastomosis, and so the decision is not affected by the relatively low mortality. Within the range of probabilities used here, the decision is only minimally sensitive to the probability of success with propranolol therapy, primarily because the range (0.45 to 0.70) is small compared with other ranges. If the range were wider, the decision would be quite sensitive to success with propranolol. For example, if the probability of success with propranolol therapy were quite low (0.10), then most cardiologists would recommend anastomosis; but if the probability were high (0.80), then most patients would receive propranolol initially and a delay in intracardiac repair. The expected lifetimes for the patient in these two situations are quite different and the decision would therefore be sensitive to the probability of success with propranolol therapy.

Decision analysis also indicated that the preferred course of treatment for a 6 month old infant with tetralogy of Fallot in our institution is administration of propranolol followed by later intracardiac repair. It revealed that if in the future we have reason to believe that the early mortality of intracardiac repair in a young infant is 10 percent or less, then we should choose to perform primary intracardiac repair. According to the analysis, the least preferred choice is primary aorticopulmonary anastomosis. These conclusions were obtained using our estimates of probabilities and expected lifetimes. However, any clinician can substitute values from his own institution in Table I, expand Figure 2, calculate expected values (Table III) and reach conclusions for his own patients.

Implications: We are in the process of refining our decision tree to make it more useful; the present one refers only to mortality. Morbidity may be included in terms of likelihood of cerebrovascular accident and bacterial endocarditis. Patients are described only in terms of age and weight. Other factors, such as preoperative hemoglobin level,[22] anatomy of the pulmonary arteries and right ventricle[23,24] and left ventricular size,[25] may affect outcome and we plan to assess their relative importance. The clinical variables may then be characterized preoperatively not only by age and weight, but also by pulmonary arterial anatomy and other factors found to be important. The probability of occurrence of each event in the decision tree can then be calculated for patients described by numerous variables with the methods used for this calculation in a patient described by the two variables age and weight. Even without these refinements and extensions, it should be possible in the future to use decision analysis to help the clinician select the best course of management for patients with tetralogy of Fallot.

Pittsburgh, Pennsylvania

Seven cases of absent right superior vena cava with persistent left superior vena cava and normal situs were diagnosed at Children's Hospital of Pittsburgh. All patients had associated cardiac defects. In two cases the diagnosis was made at autopsy, the first in 1957 in a 26 day old infant with multiple congenital defects and the second in 1965 in a 22 day old infant who had pulmonary atresia with ventricular septal defect and patent ductus arteriosus. Since 1966 absent right superior vena cava has been diagnosed at cardiac catheterization in five children. Three of these children have had surgery, two for subaortic stenosis and one for an atrial septal defect. One has an insignificant atrial septal defect and the fifth has a ventricular septal defect. The electrocardiogram of four reveals a short P-R interval and a leftward frontal plane axis of the P wave, suggesting a low atrial focus. None has had any significant conduction problem. All five children are living and well; the oldest has survived 13 years postoperatively. Certain precautions are necessary should corrective cardiac surgery or transvenous pacemaker insertion be necessary.

Absence of the right superior vena cava with a persistent left superior vena cava is rare. At Children's Hospital of Pittsburgh we undertook a study to determine the experience in this institution. Because absence of the right superior vena cava may be normal in cases of heterotaxia, cases with mirror image dextrocardia, situs inversus and visceral transposition were excluded. In 4,825 cardiac catheterizations performed between July 1966 and June 1978, five cases of absent right superior vena cava (0.1 percent) were diagnosed. It is unlikely that any case was overlooked during this period because it is the hospital's policy to enter the right superior vena cava during cardiac catheterization, even in infants. The hospital's heart museum contains 1,550 hearts with congenital defects; 2 of these hearts (0.13 percent) show absence of the right superior vena cava. During the 21 years after diagnosis of the first case, a total of 3,804 postmortem examinations were performed and the incidence rate of absent right superior vena cava in this miscellaneous group was 0.053 percent. A review of published reports revealed 60 cases with absent right superior vena cava and situs solitus; 49 were diagnosed when congenital cardiac defects were suspected and 11 when arrhythmias developed. This report describes the seven cases encountered at this hospital, potential problems during cardiac surgery and the electrocardiographic abnormalities in this anomaly and their clinical importance.

Case Reports

Case 1: A premature male infant with Down's syndrome and multiple congenital anomalies was found dead in his crib at age 26 days. In addition to absence of the right and persistence of the left superior vena cava, a very large coronary sinus, transposition of the great arteries, a single ventricle, a common atrioventricular (A-V) valve and a bicuspid pulmonary valve were found at autopsy.[1]

Case 2: A 1.8 kg girl, born 2 weeks prematurely, was admitted to this hospital at age 14 days because of increasing cyanosis. Pulmonary atresia, ventricular septal defect and patent ductus arteriosus were diagnosed at cardiac catheterization and a Blalock-Taussig systemic to pulmonary arterial anastomosis was performed. The infant initially showed improvement but died on the 22nd day of life. In addition to the previous diagnoses, autopsy revealed an absent right superior vena cava (above the azygos vein) and a persistent left superior vena cava that drained into the right atrium through a large coronary sinus. Thrombosis of the Blalock-Taussig connection had occurred. The electrocardiogram is not available for study.

Case 3: An 8 year old boy with discrete subaortic stenosis was catheterized by way of the right basilic vein. The catheter passed across the mid line and down a left superior vena cava to the coronary sinus where it entered the right atrium. A venogram revealed no right superior vena cava (Fig. 1). He underwent resection of the subaortic membrane at age 9 years and again 4 years later for recurrent obstruction. With each procedure the inferior vena cava was cannulated through the right atrial appendage (or its stump). The left superior vena cava was cannulated through a purse-string suture in the right atrium and the cannula guided by palpation through the coronary sinus into the left superior vena cava. Despite coronary sinus rhythm (Fig. 2) the child experienced arrhythmia only at the end of the first operation when it was difficult to defibrillate the heart and immediately postoperatively when he had a period of supraventricular tachycardia. The electrocardiographic findings in Cases 3 to 7 are summarized in Table I.

Case 4: A 6 year old girl with a similar systemic venous anomaly plus discrete subaortic stenosis and an anomalous right subclavian artery underwent cardiac catheterization. One year later she underwent excision of the subaortic membrane. Cannulation was carried out by the technique described in Case 3.

Case 5: At cardiac catheterization this 3 year old girl was found to have an atrial septal defect in addition to an absent right and a persistent left superior vena cava. At operation an atretic cord in the usual area of the right superior vena cava was found but no azygos vein was identified. The inferior vena cava was cannulated through the right atrial appendage and partial cardiopulmonary bypass instituted. An atriotomy was made diagonally from the superior lateral portion of the right atrium toward the inferior vena cava. A cardiotomy suction cannula was used to control the left superior vena caval flow through the coronary sinus. Because the atrial septal defect was large (2 cm in diameter) and was near the coronary sinus a knitted Dacron® patch was used to close the defect. On completion of the procedure the coronary sinus was visualized and it had not been compromised by the patch. The child has continued to do well, but there have been some electrocardiographic changes (Table I).

Case 6: A 9 1/2 year old boy had cardiac catheterization, which confirmed absence of the right and persistence of the left superior vena cava draining into the coronary sinus. In addition, the boy had a very small atrial septal defect that did not require closure.

Case 7: A 6 year old girl with Down's syndrome was found at cardiac catheterization to have the vena caval anatomy described in previous cases and a ventricular septal defect. Closure of the defect has not been performed but cannulation will be similar to that in Case 3.

Discussion

Incidence: Absent right superior vena cava with persistent left superior vena cava was first reported in 1862 (Ref. 9 of Karnegis et al.[2]). When the right superior vena cava is absent there is always a left superior vena cava that usually empties by way of the coronary sinus into the right atrium.[3] However, the left superior vena cava may join the left atrium directly.[4–6] The incidence rate of persistent left superior vena cava has been estimated to be 2 percent in congenital heart disease with situs solitus, but it is higher (40 percent) when there is abnormal situs.[7] There are no accurate statistics of the comparative incidence of persistent left superior vena cava with or without a right superior vena cava. Winter[8] reviewed 170 proved cases of totally persistent left superior vena cava and found absence of the right superior vena cava in 31. In 6 of the 31, the left superior vena cava entered the left atrium or a common atrium directly. However, cases of transposition of the viscera and situs were included. Winter analyzed 28 cases of left superior

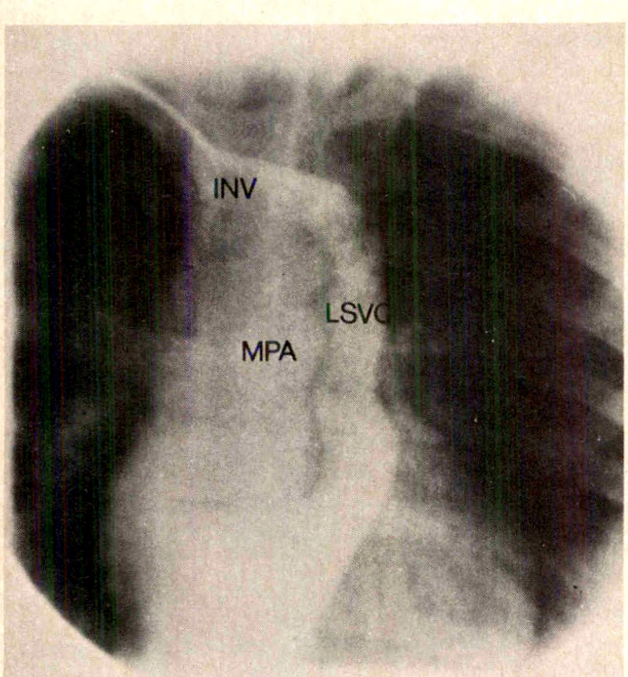

FIGURE 1. Case 3. With the catheter in the innominate vein (INV) contrast medium is injected, showing the left superior vena cava (LSVC) and no right superior vena cava. MPA = main pulmonary artery.

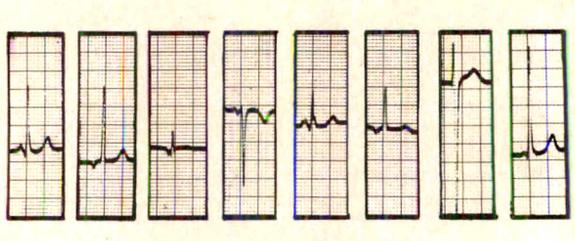

FIGURE 2. Case 3. Electrocardiogram showing upright P wave in lead I and inverted P wave in leads II and III.

vena cava in his own series and reported that in two of these the upper segment of the right superior vena cava had lost continuity with the lower segment. The latter segment received the azygos vein and entered the right atrium. Karnegis et al.[2] collected 29 single cases of absent right superior vena cava and persistent left superior vena cava reported between 1862 and 1964 and added 1 of their own. Since then, 30 additional reports have been collected and are summarized in Tables II[4–6,8–19] and III.[3,20–29] To these 60 cases we add our 7 cases, making a total of 67.

Embryology: The embryology of this systemic venous anomaly has been discussed elsewhere.[7,10] Because an atretic remnant of the right superior vena cava occasionally persists, the time of atrophy must vary. However, if the left superior vena cava enters the right atrium by way of the coronary sinus the atrophy must occur before the left cava has lost its continuity with the left duct of Cuvier. In contrast, if the left superior vena cava enters the left atrium directly, the normal development would have been arrested earlier and the sinus venosus may never have been absorbed into the right atrium, in which case the coronary sinus may be absent.[6,10]

Surgical implications: Absence of the right superior vena cava may pose problems during cardiac surgery. Early in the experience of open heart surgery it was recommended that a left superior vena cava found by the surgeon not be ligated.[7] This recommendation is important when it is not known if a right superior vena cava is present or if there is adequate connection between the two superior venae cavae. In doubtful cases, pressure in the left superior vena cava above a temporary occlusion may be measured. If it is more than 15 mm Hg, the vessel cannot be safely ligated and must be cannulated at the time of arterial bypass surgery.[13] In our Case 5 the inferior vena cava and a left superior vena cava were cannulated in the presence of an atrial septal defect; care was taken to protect the area of the coronary sinus from trauma. It has been suggested that the left superior vena caval cannula be advanced up the cava until its tip lies just inside the pericardium,[9] keeping it away from the coronary sinus because the atrial pacemaker may be in that area[12,30] and could be traumatized.

If the atrial septum is intact and the left superior vena cava enters the left atrium directly the interatrial septum will have to be incised before the anomalous venous trunk can be cannulated.[4,5] Furthermore, when the systemic venous return from the upper half of the body flows directly into the left atrium, the right atrium may be too small to accept the increased flow from the left superior vena cava when it is transferred to the right atrium. Enlargement of the right atrium by reseptation of the two atria may be necessary in such cases.[16] Successful transfer of the left superior vena cava to the right atrial appendage has been described by Shumacker et al.[11] In an unusual case, Krayenbuhl and Lincoln[6] used a baffle to redirect the total systemic venous return from the left superior vena cava to the right atrium. When the right atrium does not need to be opened, as in our patients with subaortic stenosis (Cases 3 and 4), the method of cannulation is that described in Case 3.

Arrhythmias and electrocardiographic changes: Arrhythmias may be encountered when there is an absent right and persistent left superior vena cava to the coronary sinus as demonstrated in the 11 reported cases summarized in Table III. All but one patient (Case 9)[3] was an older adult who required a pacemaker. Abnormalities of the conduction system associated with this

* Not stated.
† Absent coronary sinus.
‡ Diagnosed at surgery for neurofibroma.
§ Upper right pulmonary vein to innominate vein.
A = autopsy; ACS = absent coronary sinus; ARS = anomalous right subclavian artery; ASD = atrial septal defect; C = catheterization; CMV = cleft mitral valve; CS = coronary sinus; DORV = double outlet right ventricle; LA = left atrium; LSVC = left superior vena cava; MSR = mitral stenosis, rheumatic; OPD = ostium primum defect; PAR = partial anomalous pulmonary venous connection; PS = pulmonary stenosis; RA = radionuclide angiography; RAA = right aortic arch; S = surgery; SIA = single atrium; TASVC = total anomalous systemic venous connection; TOF = tetralogy of Fallot; VAS = vascular ring; VSD = ventricular septal defect.

venous anomaly have further been emphasized by James et al.,[3] who made a detailed study in two teenage boys. One died suddenly and the other died of an arrhythmia 16 days after repair of a ventricular septal defect.[2] The first patient had a small sinus node and the second had a mass of polypoid tissue blocking the sinus nodal artery. Both boys had basically similar histologic findings. In both, the A-V node was fragmented and stretched out over a large coronary sinus. Histologically there was disorganization and fetal dispersion of the conduction tissue throughout the A-V node and the bundle of His. Both also had prominent venous lacunae in the A-V node. James et al. speculated on the effect of these histologic abnormalities on the electric instability of hearts with a persistent left superior vena cava draining into the coronary sinus.

Other investigators have emphasized the electrocardiographic findings that may be associated with a persistent left superior vena cava. Coronary sinus rhythm, with an upright P wave in lead I and an inverted P wave in leads II and III,[31] has been related to this anomaly.[12,30] Table I lists the electrocardiographic data in our five surviving patients. Four patients manifest left axis deviation of the P wave in the frontal plane, thus meeting the criteria for coronary sinus rhythm[12] (Fig. 2). When a persistent left superior vena cava drains into the coronary sinus there is a large ostium with adjacent nodal tissue that represents the embryonic pacemaker cells seen at the junction of the left cardinal vein and the left horn of the sinus venosus in the embryo.[32] Because the A-V node originates from the same area,[32] it is possible that the conduction tissue that appears to extend as a tail around the coronary sinus is an alteration of the A-V node by the enlarged coronary sinus. However, this group of pacemaker cells electrophysiologically resembles the sinus node,[31] and may represent persistence of a separate node. Electrophysiologic studies at the time of cardiac catheterization

TABLE III

Eleven Reported Cases of Absent Right Superior Vena Cava With Associated Arrhythmias

Author	Case no.	Age (yr) Sex	Cardiac Problems	ECG Arrhythmias	Paced	Results
Harthorne[20] (1969)	1	76M	Angina	CHB	Yes*	Good
Kukral[21] (1971)	2	73M	SAA, CHF, CAD	CHB	Failed	Died

McWilliams[29] (1977)	11	60M	CAD, SAA	Trifasicular block	Yes	Died

* Transvenous, followed by epicardial.
† Premature ventricular contractions, atrial fibrillation, slow ventricular rate, right bundle block, left axis deviation.
‡ Permanent transvenous.
ACD = acute coronary infarct; ASHD = arteriosclerotic heart disease; CAD = coronary artery disease; CHB = complete heart block; CHF = congestive heart failure; ECG = electrocardiographic; SAA = Stokes-Adams attacks. + = thrombosis of coronary sinus; ++ = abnormal conduction system.

and histologic study of the conduction system in postmortem material may explain the electric instability in some of these hearts and determine whether it is related to the presence of a large left superior vena cava and coronary sinus, an absent right superior vena cava or an unrelated conduction tissue developmental defect.

Diagnosis: Diagnosis of absent right superior vena cava and persistent left superior vena cava is usually made at the time of cardiac catheterization or at operation or at autopsy. The anomaly may be suspected when the chest roentgenogram reveals absence of the shadow of the right superior vena cava and shows an extra structure in the area of the aortic knob and upper mediastinum (Fig. 3). With injection of contrast medium into a vein in the right arm and visualization by fluoroscopy or cineangiography it is easy to confirm the diagnosis. In recent years, the diagnosis has been made with radionuclide angiocardiography.[15]

Implications: The incidence of absent right superior vena cava and persistent left superior vena cava may be less rare than a review of published data indicates. The anomaly may not be diagnosed unless there are accompanying intracardiac defects or conduction abnormalities. However, the diagnosis may be suspected from radiographic or electrocardiographic findings and confirmed with cineangiography or radionuclide angiocardiography. In patients undergoing operation for congenital heart defects, the area about the coronary sinus should be protected during the cannulation of the left superior vena cava. Long range follow-up with careful observation of the electrocardiogram is important. Any patient with this anomaly who needs an artificial pacemaker should have the epicardial type because of the difficulty in obtaining sustained capture by a transvenous pacemaker.

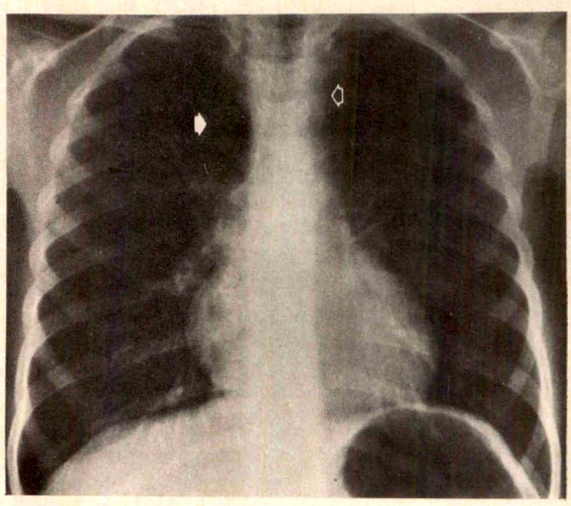

FIGURE 3. The chest roentgenogram reveals absence of the usual shadow of the right superior vena cava (**closed arrow**). The extra shadow on the left represents the left superior vena cava (**open arrow**).

Selectively Increases
Myocardial Contractility
with Consistent
Hemodynamic Improvements

Dobutrex®
Dobutamine HCl

For I.V. Injection
250 mg* in 20-ml-size vials
* Equivalent to dobutamine

Brief Summary
Consult the package literature for prescribing information.

Indications and Usage: Dobutrex® (dobutamine hydrochloride, Lilly) is indicated when parenteral therapy is necessary for inotropic support in the short-term treatment of adults with cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures.

In patients who have atrial fibrillation with rapid ventricular response, a digitalis preparation should be used prior to instituting therapy with Dobutrex.

Contraindication: Dobutrex is contraindicated in patients with idiopathic hypertrophic subaortic stenosis.

Warnings: 1. *Increase in Heart Rate or Blood Pressure*—Dobutrex may cause a marked increase in heart rate or blood pressure, especially systolic pressure. Approximately 10 percent of patients in clinical studies have had rate increases of 30 beats/minute or more, and about 7.5 percent have had a 50-mm Hg or greater increase in systolic pressure. Reduction of dosage usually reverses these effects promptly. Because dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of developing rapid ventricular response. Patients with preexisting hypertension appear to face an increased risk of developing an exaggerated pressor response.

2. *Ectopic Activity*—Dobutrex may precipitate or exacerbate ventricular ectopic activity, but it rarely has caused ventricular tachycardia.

Precautions: 1. **During the administration of Dobutrex, as with any adrenergic agent, ECG and blood pressure should be continuously monitored. In addition, pulmonary wedge pressure and cardiac output should be monitored whenever possible to aid in the safe and effective infusion of Dobutrex.**

2. Hypovolemia should be corrected with suitable volume expanders before treatment with Dobutrex is instituted.

3. Animal studies indicate that Dobutrex may be ineffective if the patient has recently received a beta-blocking drug. In such a case, the peripheral vascular resistance may increase.

4. No improvement may be observed in the presence of marked mechanical obstruction, such as severe valvular aortic stenosis.

• *Usage Following Acute Myocardial Infarction*—Clinical experience with Dobutrex following myocardial infarction has been insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

Usage in Pregnancy—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

Pediatric Use—The safety and effectiveness of Dobutrex® (dobutamine hydrochloride, Lilly) for use in children have not been studied.

Drug Interactions—There was no evidence of drug interactions in clinical studies in which Dobutrex was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

Adverse Reactions: *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10 to 20-mm increase in systolic blood pressure and an increase in heart rate of five to 15 beats per minute have been noted in most patients. (See Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5 percent of patients have had increased premature ventricular beats during infusions. These effects are dose related.

Miscellaneous Uncommon Effects—The following adverse effects have been reported in 1 to 3 percent of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex have been observed.

Longer-Term Safety—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

Overdosage: In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex until the patient's condition stabilizes. Because the duration of action of Dobutrex is short, usually no additional remedial measures are necessary.

Administration and Dosage: *Reconstitution and Stability*—Dobutrex® (dobutamine hydrochloride, Lilly) is incompatible with alkaline solutions and should not be mixed with products such as 5% Sodium Bicarbonate Injection.

Dobutrex may be reconstituted with Sterile Water for Injection or 5% Dextrose Injection. To reconstitute, add 10 ml of diluent to Vial No. 7051, Dobutrex, 250 mg. If the material is not completely dissolved, add an additional 10 ml of diluent. The reconstituted solution may be stored under refrigeration for 48 hours or at room temperature for six hours.

Reconstituted Dobutrex must be further diluted to at least 50 ml prior to administration in 5% Dextrose Injection, 0.9% Sodium Chloride Injection, or Sodium Lactate Injection. Intravenous solutions should be used within 24 hours.

Solutions containing Dobutrex may exhibit a color that, if present, will increase with time. This color change is due to slight oxidation of the drug, but there is no significant loss of potency during the reconstituted time periods stated above.

Recommended Dosage—The rate of infusion needed to increase cardiac output usually ranges from 2.5 to 10 mcg/kg/min (see table). On rare occasions, infusion rates up to 40 mcg/kg/min have been required to obtain the desired effect.

Rates of Infusion for Concentrations of 250, 500, and 1000 mcg/ml

Drug Delivery Rate (mcg/kg/min)	Infusion Delivery Rate 250 mcg/ml* (ml/kg/min)	500 mcg/ml† (ml/kg/min)	1000 mcg/ml‡ (ml/kg/min)
2.5	0.01	0.005	0.0025
5	0.02	0.01	0.005
7.5	0.03	0.015	0.0075
10	0.04	0.02	0.01
12.5	0.05	0.025	0.0125
15	0.06	0.03	0.015

*250 mg per liter of diluent
†500 mg per liter or 250 mg per 500 ml of diluent
‡1000 mg per liter or 250 mg per 250 ml of diluent

The rate of administration and the duration of therapy should be adjusted according to the patient's response, as determined by heart rate, presence of ectopic activity, blood pressure, urine flow, and, whenever possible, measurement of central venous or pulmonary wedge pressure and cardiac output.

Concentrations up to 5000 mcg/ml have been administered to humans (250 mg/50 ml). The final volume administered should be determined by the fluid requirements of the patient.

"...prolonged beneficial effects

upon exertionally induced angina* in patients with ischemic heart disease."[1]

A double-blind, controlled study of 28 patients employing maximal treadmill exercise stress tests.

1. Antianginal efficacy of oral therapy with isosorbide dinitrate capsules. Lee G, Mason DT, Amsterdam EA, Miller RR, and DeMaria, AN. *Chest* 73:327-333, 1978.

ISORDIL® TEMBIDS® CAPSULES

(ISOSORBIDE DINITRATE) SUSTAINED-ACTION CAPSULES, 40 mg

- **gradual release provides up to ten hours of sustained prophylaxis against angina pectoris attacks**
- **bid dosage is frequently satisfactory to prevent angina attacks...dosage range 1 capsule bid to qid**
- **stable...retains potency without significant loss or variation under normal conditions (room temperature, c 73 F)**

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

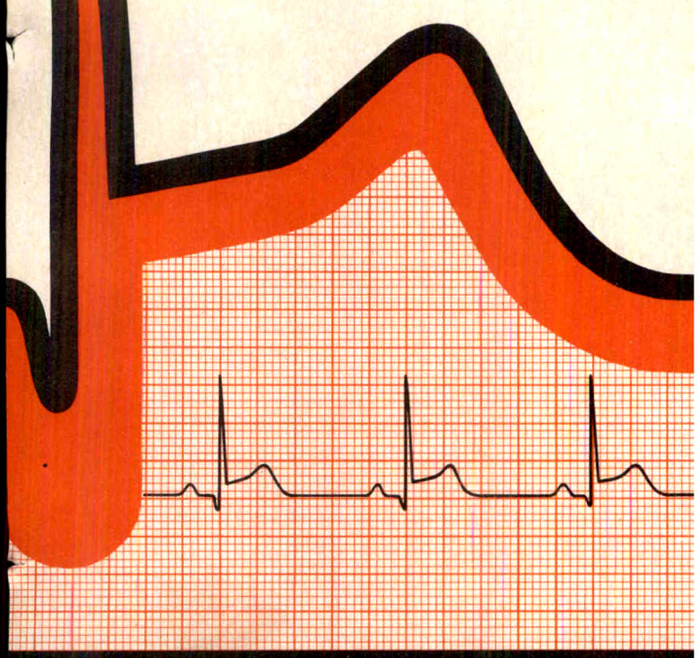
TEMBIDS®—TRADEMARK FOR SUSTAINED-ACTION CAPSULES

You and Telemed recognize th difference between these contours.

Other computer ECG programs don't.



Identical junctional ST segment elevations... different contour shapes. What's the significance? Both the electrocardiographer and the Telemed Program recognize it immediately. Other computer ECG programs don't consider wave form shape in their analyses.

Since the Telemed Program parallels the associative logic of the electrocardiographer, it also correlates patient age, sex, body build, clinical history and current drug regimen with the ECG trace and reports their related clinical significance.

These are two of the many reasons why no other computer ECG analysis program can match the clinical relevance and usefulness of the Telemed Program.

The Telemed Program enables the electrocardiographer to:

- Increase reading efficiency because it identifies abnormal ECG's.
- Expand his practice by saving him time and offering him 24 hour a day, 7 day a week back-up.

Hewlett-Packard's new 500 Series Patient Information Center is a substantial advance in patient monitoring.

All quotations in this brochure are a summation of comments made by medical, engineering, and administrative professionals during extensive clinical tests, trials and seminars on the 500 Series.

While the 500 Series incorporates virtually every monitoring function required of a modern microprocessor based central station, it also provides important innovations in four specific areas:

☐ It has noticeably reduced false HR alarms.
☐ It has simplified system operation to 10 function keys.
☐ It has improved the detail, display, recall and accuracy of monitoring information.
☐ It has increased system reliability through a comprehensive four-level system of self-test and self-diagnosis.

In addition, the 500 Series is so compact that it requires less than half the working space needed by most other central stations. It is modular in design so that it can be economically expanded and upgraded. And its inherent flexibility provides a broad range of price and performance features as well as functional capabilities. In short, the 500 Series is a total Patient Information Center which can serve your unit or institution for years to come.

"Now when I hear that alarm I know it's serious."

In an actual hospital test, the 500 Series showed more than an 85% reduction in false HR alarms. By using sophisticated computer techniques to identify "R" waves, the 500 Series seldom miscounts the muscle artifact and extraneous noise that account for most false alarms.

"10 major function keys make it far easier to use."

While most central station systems carry as many as 50 or 60 major function keys, the 500 Series requires only 10, since each "softkey" is a multiple function key. This means a more compact control panel with less clutter and less confusion. And the operation of the 500 Series is simplicity itself – it actually guides the staff through the use of English-like cues.

"For the first time, I've got a sharp, bright QRS right next to my patient's vital signs."

Using such techniques as a high resolution 1200 line raster scan and a 10-bit sample, the new "superaster" display in the 500 Series delivers bright QRS detail on ECG waves. In addition, words and numbers can both be displayed anywhere on the screen.

Reliable

The 500 Series is designed and built to provide the highest level of on-line consistency. Advanced circuit design, thoroughly tested parts and components, and a rigorous 14-step environmental and quality control testing procedure give the 500 Series an inherent reliability.

Dependable

Should a malfunction in the 500 Series occur, four distinct levels of self-test and self-diagnosis are available to quickly and easily detect and correct it.

Level 1 is an automatic continuous fault monitor, invisible to the operator unless a malfunction occurs.

Level 2 is a self-test that generates an internal system check as well as a list of diagnostic codes to aid in the correction. It provides a recorder strip, conveniently annotated with error codes so the operator has a hard copy of virtually any fault.

Level 3 is an extended self-test that does everything in Level 2 with the addition of a display check.

Level 4 fault detection employs a circuit analyzer board which takes command of the microprocessors and data buses facilitating component level trouble shooting using digital signature analysis.

Self-test with the 500 Series Patient Information Center is not an idle claim. It was designed and built-in at the inception, and it is a major advancement in system serviceability, convenience and cost effectiveness.

Adaptable

The modularity of the 500 Series Patient Information Center permits a variety of system configurations as well as options and functions. This "building block" approach to patient monitoring allows you to custom configure a system to best meet your individual needs.

A Choice of Systems. The 500 Series Patient Information Center is available in a Basic and a Comprehensive system. The 78501 Basic system is primarily intended for progressive care and telemetry units and provides 8 ECG traces on a single scope.

The 78502 Comprehensive system is primarily intended for intensive care and surgical units. It provides 4 six-second ECG traces. It also provides display of all monitored vital signs, other monitored waveforms, or freeze of ECG data. Optionally, 48 trend lines and eight channels of pressure processing may be added to each four-bed unit.

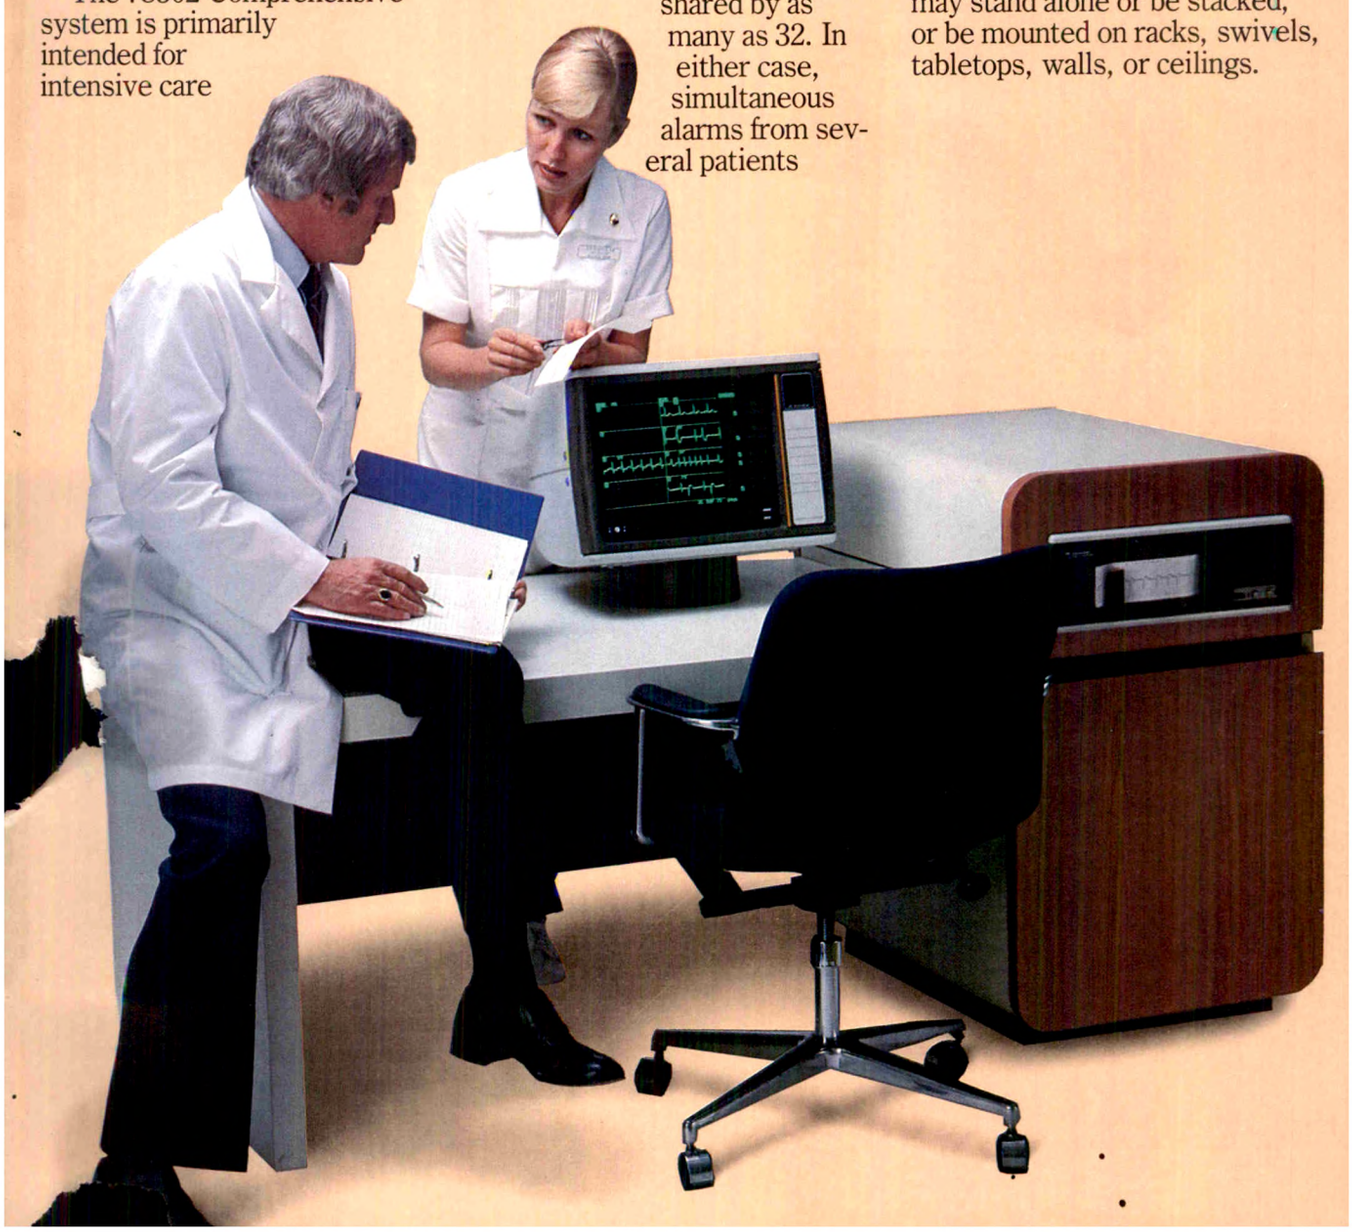
The 78520 is an arrhythmia monitoring system with a separate computer and arrhythmia data display. It can be added to either the Basic or Comprehensive system. The 78525 adds storage, recall and edit plus data management functions to either system.

Recorder Capabilities. Hewlett-Packard recorders may be dedicated to four patients or shared by as many as 32. In either case, simultaneous alarms from several patients will automatically be captured, and stacked in an electronic memory. Annotation of bed ID, time, date, alarm cause and heart rate from the time of alarm accompany the waveform on the strips.

Bedside Options. Available HP bedsides include "telemetry," "ECG only," "ECG and pressure," or "multi-parameter." Each system accommodates any combination of bedsides.

Custom Options. Both systems also offer custom configuration. Such parameters as recorder run and delay times, and bed identification may be defined for each installation.

Mounting Options. Displays may stand alone or be stacked, or be mounted on racks, swivels, tabletops, walls, or ceilings.



The Hewlett-Packard approach to critical care.

The 500 Series Patient Information Center is a tangible end product of the Hewlett-Packard approach to patient monitoring. An approach that is committed to the innovative use of new technology and the on-going design, development, manufacture and support of reliable, dependable critical care products.

Careful attention to compatibility between the 500 Series and older as well as new bedside products is another example of the HP approach. Compatibility adds longer life and utility to an institution's investment.

In addition, Hewlett-Packard returns more than 8% of every medical sales dollar to research and development. Hewlett-Packard's engineers also maintain perhaps the industry's toughest quality control standards – standards that include 14 separate environmental tests. As part of its support services, Hewlett-Packard is committed to timely installation, user and bioengineer training, as well as preventative maintenance and repair.

In every aspect of patient monitoring, Hewlett-Packard is dedicated to responsible technological advances and clinically tested procedures. You can depend on it.

Sustained Beneficial Effects of Oral Amrinone on Cardiac and Renal Function in Patients With Severe Congestive Heart Failure

THIERRY H. LeJEMTEL, MD
EDMUND KEUNG, MD
HILLEL S. RIBNER, MD
RICHARD DAVIS, MD
JOHN WEXLER, MD
M. DONALD BLAUFOX, MD
EDMUND H. SONNENBLICK, MD, FACC

Bronx, New York

Although effectiveness of oral amrinone has been demonstrated in animals, amrinone has been shown in human subjects to improve cardiac performance in the failing heart only after acute intravenous administration. Therefore, we studied the hemodynamic and renal effects of orally administered amrinone (50 to 300 mg) in 10 patients with advanced congestive heart failure. Cardiac index increased from 1.56 ± 0.41 (mean ± standard deviation) to 2.20 ± 0.43 liters/min per m^2 ($p < 0.001$); pulmonary wedge pressure decreased from 26.1 ± 5.7 to 17.0 ± 5.7 mm Hg ($p < 0.001$). Mean arterial pressure decreased from 86.0 ± 8.4 to 81.3 ± 7.7 mm Hg ($p < 0.001$) and systemic vascular resistance from 2,406 ± 603 to 1,693 ± 261 dynes sec cm^{-5} ($p < 0.001$). Heart rate was unchanged. The onset of action ranged from 30 to 120 minutes and the duration of action from 4 to 7 hours after a single oral administration. After 24 hours of continuous therapy, no tachyphylaxis to amrinone was observed. A correlation ($r = 0.62$, $p < 0.001$) was found between the oral dose of amrinone and the percent increase in cardiac index. Left ventricular ejection fraction, determined in five patients, increased from 14 ± 8 to 21 ± 8 percent ($p < 0.01$). Effective renal plasma flow, measured in six patients, increased from 186.0 ± 72.0 to 231.1 ± 88.8 ml/min ($p < 0.05$) and the glomerular filtration rate from 82.2 ± 14.9 to 110.0 ± 20.6 ml/min ($p < 0.05$). Thus, this study demonstrates the cardiotonic efficacy of orally administered amrinone in human subjects and recommends its further investigation as a therapeutic agent for the continued treatment of congestive heart failure.

Amrinone, a newly synthesized bipyridine derivative, has been shown to exert positive inotropic activity in animals.[1] In patients with severe congestive heart failure, amrinone increases cardiac output and reduces left ventricular filling pressure when given acutely as an intravenous bolus injection.[2,3] This improvement in cardiac function occurs without changes in heart rate and arterial pressure and without development of arrhythmias.[2,3]

Amrinone is unique in that its positive inotropic action is not exerted through the cell mechanisms normally attributed to either catecholamines or digitalis glycosides.[4] Catecholamines have limited long-term usefulness because they must be administered intravenously. Moreover, catecholamines can induce tachycardia and ventricular arrhythmias as well as undesirable changes in arterial pressure.[5] Digitalis glycosides are commonly administered to attain long-term enhancement of myocardial contractility and are currently the only useful oral inotropic agents. However, their beneficial hemodynamic effects, aside from those re-

sulting from control of heart rate and rhythm, appear to be modest,[6] and increased dosages are limited by untoward side effects.[7] Because of the effectiveness of oral amrinone in animals,[1] combined with the initial encouraging effects of intravenous amrinone in human subjects, the study of oral amrinone in patients with congestive heart failure is recommended.

Methods

Patients: Ten patients with chronic congestive heart failure formed the study group; six were men and four women (Table I). Six patients had ischemic cardiomyopathy and heart failure resulting from coronary artery disease, which was evidenced by myocardial infarction in two and documented by coronary angiography in four. All the angiographic studies showed severe and diffuse triple vessel coronary disease. Three patients had cardiomyopathy of unknown origin. Congestive heart failure developed in one subject after aortic and mitral valve replacement. Two patients had atrial fibrillation and the remaining eight had sinus rhythm. No patient had arterial hypertension, recent myocardial infarction or primary valve disease. The duration of heart failure ranged from 1 to 4 years. All patients except one were severely restricted in activity and were clinically in class IV, according to the criteria of the New York Heart Association.[8] Eight patients had previously been treated with oral vasodilators, seven with hydralazine, and one with prazosin. Such therapy was deemed inadequate because the patients manifested no improvement in condition and remained in severe heart failure.

Patients were admitted or in the hospital 5 days before hemodynamic evaluation. All vasodilators were discontinued at that time and a strict dietary regimen including 2 g of sodium a day was prescribed. Subjects continued to receive their usual daily doses of digitalis glycosides and diuretic drugs throughout the study period. Serum digoxin levels are noted in Table I.

The nature, potential benefits and possible risks of the study were fully explained to all patients, who then gave informed consent. The investigation protocol was approved in advance by the Committee on Clinical Investigations of the Albert Einstein College of Medicine.

Hemodynamics: After 24 hours of bed rest, the patients underwent right heart catheterization performed using a flow-directed balloon-tipped thermodilution catheter (Gould Laboratories). Mean pulmonary arterial, pulmonary wedge, and right atrial pressures were recorded on a photographic recorder (Electronics for Medicine). Cardiac output was determined with a thermodilution technique using iced 5 percent dextrose in water, and obtained in triplicate with less than 10 percent variation. Computations of cardiac output were made with a bedside computer (model S.P. 1450, Gould Laboratories) and were confirmed periodically with appropriate integration of recorded curves. Systemic arterial pressure was measured by two observers using standard cuff techniques. Mean arterial pressure was taken as diastolic pressure plus one third of the pulse pressure. Derived hemodynamic indexes were calculated as follows: Cardiac index = cardiac output/body surface area (liters/min per m^2); Stroke volume index = 1,000 cardiac index/heart rate (ml/m^2); Systemic vascular resistance = 80 (mean arterial pressure − mean right atrial pressure)/cardiac output (dyne sec cm^{-5}); Pulmonary vascular resistance = 80 (mean pulmonary pressure − pulmonary wedge pressure)/cardiac output (dyne sec cm^{-5}).

An electrocardiographic lead was monitored continuously throughout the study.

Renal function determinations: Effective renal plasma flow was determined with iodine-131 orthoiodo-hippurate (50 μCi) and glomerular filtration rate was measured with iodine-125 iothalamate (30 μCi) as previously described by Silkans et al.[9] After the simultaneous intravenous injection of the radioactive material, the disappearance of radioactivity in the plasma was sampled at 5 to 10 minute intervals over a period of 75 minutes. Curves were analyzed by visual analysis into two components and clearance calculated from the equation: clearance = (dose × slope of fast component × slope of slow component)/(the intercept of fast component × slope of the slow component) + (the intercept of slow component × the slope of the fast component).

Radionuclide imaging and ejection fraction: Left ventricular ejection fraction was determined by a gated technique that used modifications of the method described by Bacharach et al.[10] The patient's red blood cells were labeled in vivo with 15 mCi of technetium-99m pertechnetate[11] 15 minutes before study. Twenty-eight frame multigated studies were obtained in an acquisition time of 2 minutes. End-diastolic and end-systolic regions of interest were determined through modification of an automatic edge detection method.[12] After correction for background, left ventricular ejection fraction was calculated according to the formula: (ED − ES)/ED; where ED = end-diastolic counts and ES = end-systolic counts, corrected for background.

AF = atrial fibrillation; CAD = coronary artery disease; CM = cardiomyopathy; NYHA Class = New York Heart Association functional class[8]; Post MVR, AVR = status after mitral and aortic valve replacement; SR = sinus rhythm.

Amrinone administration: Patients were evaluated in the postabsorptive state. Hemodynamic responses to increasing intravenous doses of amrinone were first evaluated to establish dose and effectiveness. A washout period of 24 hours was allowed. Then two sets of baseline hemodynamic measurements were made at 1/2 hour intervals at least 6 hours after the daily doses of digitalis and diuretic drugs. Amrinone was administered orally as a single dose in an amount that, when given intravenously, produced a rise in cardiac index of at least 40 percent or reduced pulmonary wedge pressure to within the normal range (12 mm Hg or less). Hemodynamic measurements were performed 30 minutes later and then hourly until values returned to baseline levels. On subsequent days, this procedure was repeated while the daily oral dose of amrinone was increased by increments of 50 to 100 mg as long as the pulmonary wedge pressure remained elevated. To determine whether sustained hemodynamic benefit could be obtained, oral amrinone was administered in a constant dose at 8 hour intervals for 24 hours in five patients.

Statistical methods: Maximal hemodynamic changes, renal function determinations and ejection fraction data were tested for significance using the Student's paired t test. Statistical significance for duration of action and effects of consecutive administration of amrinone are based on the results of analysis of variance techniques. Two-way analysis of variance was employed to test for differences between values in control and amrinone therapy and for carryover effects. If statistical significance was obtained, further individual comparison testing was done using Dunnett's test. Results are expressed as the mean ($\bar{x}$) ± standard deviation (SD) and are considered significant at the $p < 0.05$ level.

Results

Hemodynamics: The cardiac index in the control state was less than 2.5 liters/min per m^2 whereas pulmonary wedge pressure exceeded 15 mm Hg in all patients. The maximal hemodynamic effects of an oral dose of amrinone (Table I) are depicted in Figure 1 and listed in Table II for all 10 patients. Mean cardiac index increased from 1.56 ± 0.41 to 2.20 ± 0.43 liters/min per m^2 ($p < 0.001$). There were decreased values for mean pulmonary wedge pressure (from 26.1 ± 5.6 to 17.0 ± 5.7 mm Hg; $p < 0.001$), mean right atrial pressure (from 10.4 ± 5.7 to 4.5 ± 3.5 mm Hg; $p < 0.01$), mean arterial pressure (from 86.0 ± 8.4 to 81.3 ± 7.7 mm Hg; $p < 0.001$) and mean systemic vascular resistance (from 2,406 ± 603 to 1,693 ± 261 dynes sec cm^{-5}; $p < 0.001$). Heart rate was not changed significantly. Patients responded

similarly whether they had atrial fibrillation or sinus rhythm.

The time course of hemodynamic response to amrinone administration was studied in eight patients (Fig. 2). The maximal hemodynamic effects of amrinone occurred 1 to 4 hours after the oral administration of the drug. Variability was also observed in the onset of action, which ranged from 30 to 120 minutes. Although the hemodynamic effects of amrinone were still present 6 hours after the oral administration, only the reduction in systemic vascular resistance was still significant. The increments in cardiac index and stroke volume index were statistically significant up to 4 hours after amrinone administration, whereas the decrease in pulmonary wedge pressure was significant only at 2 and 3 hours. The decrease in mean arterial pressure was modest and did not reach statistical significance.

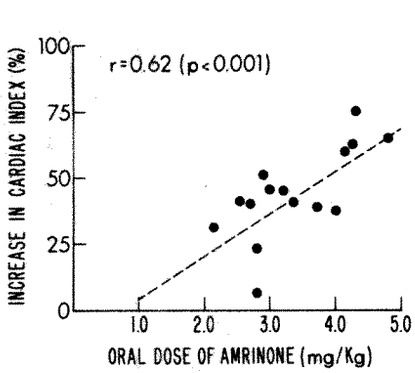

FIGURE 4. Maximal increase in cardiac index (%) as a function of oral amrinone dose. Fifteen doses were given in eight patients. r = correlation coefficient.

The maximal changes in cardiac index and pulmonary wedge pressure are depicted in Figure 3 for three consecutive doses of oral amrinone given at 8 hour intervals in five patients. After each dose, cardiac index was significantly increased ($p < 0.01$) and pulmonary wedge pressure significantly decreased ($p < 0.01$) compared with the baseline values for each administration. Furthermore, 8 hours after the second dose of amrinone, the cardiac index was significantly increased ($p < 0.01$) when compared with the initial value before to amrinone administration. This finding is consistent with a cumulative effect of the drug. No tachyphylaxis to amrinone was observed at any time.

In two patients (Cases 4 and 9) the dose of amrinone was not increased because the pulmonary wedge pressure decreased to the normal range (below 12 mm Hg). The maximal increases in cardiac index at each dose of amrinone for the remaining eight patients are illustrated in Figure 4. There was a correlation between the dose of amrinone and the relative change in cardiac index ($r = 0.62$, $p < 0.001$). Because the pulmonary wedge pressure did not fall below 12 mm Hg in most patients, it is likely that further increases in cardiac index could have been obtained with larger doses of amrinone. Indeed, in no patient was the dose increased to tolerance, and a leveling of the dose-response curve was not established. The administration of further doses was limited by the number of days that a Swan-Ganz catheter could be tolerated by a given patient. Thus, the limits of drug tolerance necessary to obtain a maximal effect or to induce toxicity, if any, were not necessarily reached.

Ejection fraction: Left ventricular ejection fraction determined by radionuclide imaging prior to amrinone

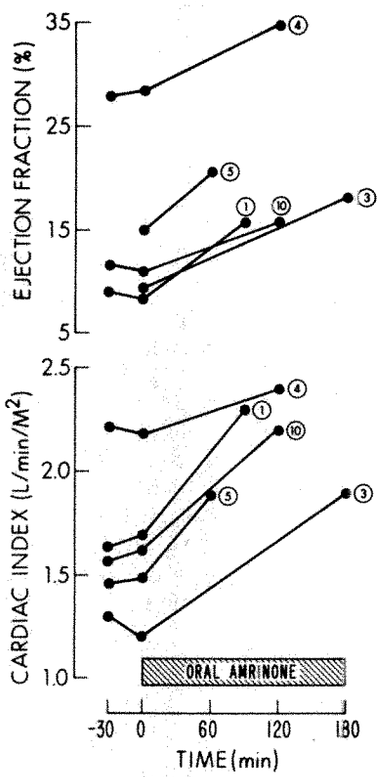

FIGURE 5. Radionuclide ejection fraction before and after administration of a single dose of amrinone with simultaneous cardiac index; these data were obtained in the five patients denoted by **numbered circles.**

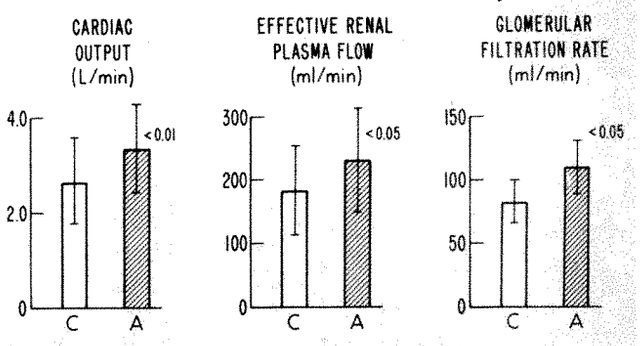

FIGURE 6. Effect of oral amrinone to increase effective renal plasma flow (six patients) and glomerular filtration rate (four patients) together with cardiac output. C = control period; A = amrinone; **bars** represent mean value ± standard deviation.

administration and at maximal increase in cardiac index was determined in five patients while they were hemodynamically monitored. The simultaneous changes in ejection fraction and cardiac index are shown in Figure 5. Ejection fraction increased from a control value of 14 ± 8 to 21 ± 8 percent ($p < 0.01$) and the cardiac index from 1.60 ± 0.36 to 2.14 ± 0.24 liters/min per m^2 ($p < 0.01$). In each patient, the absolute increase in ejection fraction was equal to or greater than 5 percent, with an overall increase averaging 7 percent. The time required to reach the maximal increase in cardiac index was variable, as previously mentioned.

Renal function: Changes in effective renal plasma flow and glomerular filtration rate were evaluated in six and four patients, respectively (Fig. 6, Table III). The renal function studies were initiated shortly after the maximal increase in cardiac index was noted. The cardiac index recorded for each patient was obtained in the middle of the determinations. Both effective renal blood flow and glomerular filtration fraction increased significantly ($p < 0.05$). The improvement in renal blood flow and glomerular filtration rate was associated with a concomitant rise in cardiac index. The filtration fraction did not change significantly (0.43 to 0.48) during amrinone administration.

Side effects: No overt clinical manifestations of toxicity were observed during administration of amrinone. One patient (Case 8) experienced a transient increase in frequency of ventricular premature complexes (15/min) at peak hemodynamic effect compared with the value during prior amrinone administration (less than 5/min). In the remaining nine patients, no electrocardiographic changes were noted in serial tracings or rhythm strips performed before, during or after amrinone therapy. (See Addendum for further data.)

Discussion

This study establishes the efficacy of *orally* administered amrinone in improving cardiac performance in patients with severe heart failure. This improvement was observed in all patients studied even though they were all severely ill and poorly responsive to conventional therapy, including digitalis glycosides, diuretic drugs and vasodilators.

The cardiotonic action of amrinone was characterized by an increase in cardiac output with substantial decreases in both right and left ventricular filling pressures and in peripheral vascular resistance. These beneficial hemodynamic effects were achieved with no evident untoward side effects. Heart rate was not altered and the reduction in mean arterial pressure was modest.

Mechanisms of beneficial hemodynamic effects: The improvement in ventricular performance induced by amrinone in patients with heart failure appears to result from a direct stimulation of the depressed myocardium as well as a decrease in peripheral vascular resistance. Some of this latter effect may reflect withdrawal of enhanced sympathetic constrictor tone consequent to the improvement in cardiac performance, as noted previously in response to digitalis therapy in patients with severe heart failure.[13] A direct vasodilator effect of amrinone on the systemic resistance vessels has also been demonstrated in the isolated perfused hind limb of the dog (A. Alousi, personal communication). This direct vasodilatory effect may help to explain the decrease in arterial blood pressure noted in normal human subjects consequent to administration of relatively large doses of amrinone.[14] Modest reductions in blood pressure were also found in the present study. A simultaneous increase in myocardial contractility is supported by studies of isolated cardiac muscle preparations,[1,4] by strain gauge measurements made on the surface of the dog ventricle,[1,4] and by increments in rate of left ventricular pressure development noted in human subjects.[2]

Duration of effects of oral amrinone: In most patients, the duration of action of a single oral dose of amrinone ranged from 4 to 7 hours. Moreover, in patients who received consecutive doses of amrinone at 8 hour intervals, persistent increases in cardiac output remained 8 hours after the second dose. No evidence of tachyphylaxis was noted over a 24 hour period. Therefore, for long-term therapy with amrinone, administration of the oral drug every 8 to 12 hours may be sufficient to obtain a persistent improvement in cardiac performance. These initial studies to demonstrate hemodynamic improvement by oral amrinone in the presence of severe ventricular failure with no side effects or tachyphylaxis suggested its usefulness for long-term therapy.

Mechanisms of improved renal function: Renal plasma flow before therapy was reduced in our patients. This occurrence has been well demonstrated in patients with advanced heart failure.[15] Glomerular filtration rate was decreased to a lesser degree, and the renal filtration fraction was increased. The increase in filtration fraction in heart failure has been attributed to intense vasoconstriction of efferent arterioles to the glomeruli, which tends to maintain glomerular filtration pressure.[15] Mediation of this constriction has been attributed to increased activity of both the sympathetic nervous system and the renin-angiotensin system.[15] After amrinone administration, the improvement in cardiac output was associated with an increase of both renal plasma flow and glomerular filtration rate. However, filtration fraction was unchanged. The persistence of an elevated filtration fraction in our patients, despite the salutary circulatory response to amrinone, suggests that enhanced sympathetic tone and increased circulating angiotension II were still present and may have prevented renal function from returning to a completely normal pattern. Whether further improvement in renal function will occur over a longer therapeutic period remains to be studied.

Ejection fraction by radionuclide imaging: Oral amrinone induced an absolute increase in left ventricular ejection fraction that varied from 5 to 9 percent, as obtained with radionuclide imaging using with use of a gated technique. The variability of ejection fraction determined by multiple gated blood pool imaging has recently been estimated to be less than ± an absolute 2.5 percent in patients with an abnormal heart.[16] Thus, increases in noninvasively determined ejection fraction observed in our patients after amrinone are probably significant and are in agreement with the improvement in ventricular function simultaneously demonstrated by invasively measured hemodynamic values. Radionuclide imaging appears to provide an objective and sensitive means of evaluating long-term therapy. Echocardiography has the disadvantage of reflecting a limited segmental wall motion rather than ventricular volume changes.

Amrinone in ischemic heart disease: In this study, patients with heart failure due to either congestive cardiomyopathy of unknown origin or end-stage ischemic heart disease responded equally well to administration of amrinone. In the latter case, no evidence of increased ischemia was observed and hemodynamic improvement was sustained with no chest pain or electrocardiographic changes. Indeed, one may anticipate that even in the presence of obstructive coronary artery disease, treatment of ventricular failure may be beneficial by reducing oxygen requirements of the ventricle consequent to a reduction in ventricular volume and, hence, wall tension. This latter effect might outweigh any effect of increased contractility to augment oxygen consumption.[17] Moreover, a decrease in diastolic pressure in the ventricle may allow better perfusion of ischemic portions of the ventricular wall.[18]

Mode of action and role of combined digitalis therapy: The mode of action of amrinone has yet to be defined. The drug does not effect the biochemical mechanisms associated with the action of either catecholamines or digitalis glycosides. Thus, catecholamine stores in the heart are not required for amrinone's action[4] and the drug is effective despite adrenergic blockade.[1,4] The effect of amrinone to increase con-

tractility is additive to that of digitalis glycosides. Indeed, all of our patients were already taking digitalis and no untoward effects resulted from combined therapy.

In the presence of atrial fibrillation, ventricular rate can, and may need to be, controlled with digitalis glycosides. Amrinone does not affect this action of digitalis nor does it appear to alter atrioventricular conduction as judged from an unchanged P-R interval in the electrocardiogram. We have not yet administered amrinone to patients with atrial fibrillation who were not taking digitalis. In patients with atrial fibrillation who were receiving digitalis glycosides, amrinone did not change ventricular rate. Thus, glycosides may be required for control of ventricular rate, and ventricular contractility can then be further augmented with amrinone.

In summary, amrinone is a newly synthesized cardiotonic agent that, when orally administered, is highly effective in augmenting ventricular performance of the failing human heart. The beneficial effects, which occurred with only a slight reduction in blood pressure, were not accompanied by significant changes in heart rate or other side effects. Tachyphylaxis did not occur. The action of amrinone is mediated by an unknown mechanism that differs from that attributed to either catecholamines or digitalis glycosides.

Addendum

Since this report was submitted for publication, thrombocytopenia developed in two of the patients described. Beneficial oral therapy had been proceeding for 4 and 8 weeks and the blood platelet count decreased to 40,000 and 19,000 per mm^3, respectively, with a dose level of amrinone of 450 mg/day. Other elements of the peripheral blood were not altered and bone marrow studies showed no evidence of precursor suppression. Amrinone therapy was discontinued and the platelet counts returned to normal levels in both cases.

Use of Ajmaline In Patients With the Wolff-Parkinson-White Syndrome to Disclose Short Refractory Period of the Accessory Pathway

HEIN J. J. WELLENS, MD, FACC
FRITS W. BÄR, MD
ANTON P. GORGELS, MD
EDUARD J. VANAGT, MD

Maastricht, The Netherlands

Ajmaline given intravenously produced complete anterograde block in the accessory pathway of 32 of 59 patients with the Wolff-Parkinson-White syndrome. An electrophysiologic investigation performed 1 day later revealed that failure of ajmaline to produce complete anterograde block in the accessory pathway corresponded to a short refractory period of this pathway (less than 270 ms). The use of ajmaline intravenously is advanced as a reliable and rapid procedure for identifying those patients with the Wolff-Parkinson-White syndrome who have a short refractory period of the accessory pathway and are possibly at risk of circulatory insufficiency or sudden death if atrial fibrillation supervenes.

Atrial fibrillation can be a life-threatening arrhythmia in patients with the Wolff-Parkinson-White syndrome.[1–6] An important factor, among several that determine the ventricular rate during atrial fibrillation, is the duration of the refractory period of the accessory atrioventricular (A-V) pathway in the A-V direction.[7,8] Deterioration of atrial fibrillation into ventricular fibrillation has been reported in patients with a short refractory period of the accessory pathway in an anterograde direction.[9] In patients with the Wolff-Parkinson-White syndrome it is important to know the duration of the refractory period of the accessory pathway in the anterograde direction in order to assess the risk of sudden death in that patient if atrial fibrillation supervenes. In this report we describe how ajmaline can be used to obtain this information.

Methods

Patients: Fifty-nine patients were studied: All had the electrocardiographic features of the Wolff-Parkinson-White syndrome. Their ages ranged from 7 to 61 years; 45 patients were male and 14 female. Thirty-nine patients had electrocardiographic documentation of a regular supraventricular tachycardia. In 10 patients the electrocardiogram revealed atrial fibrillation and in 6 patients both atrial fibrillation and regular supraventricular tachycardia. Four patients were asymptomatic. In all but one patient showing a regular tachycardia a circus movement tachycardia with retrograde conduction over the accessory pathway could reproducibly be initiated during the stimulation study. The remaining patient manifested a circus movement tachycardia with anterograde conduction over the accessory pathway. The programmed electric stimulation study was used to locate the accessory pathway: The pathway was located between the right atrium and the right ventricle in 13 patients, between the left atrium and the left ventricle in 32 and in the septum in 14.

Protocol: The following protocol was used in all patients. All medication was withheld for at least 4 days.

1. Twenty-four hours before a programmed electric stimulation study, and after a 12 lead electrocardiogram revealed sinus rhythm with the Wolff-Parkinson-White abnormality, 50 mg of ajmaline was given intravenously over a

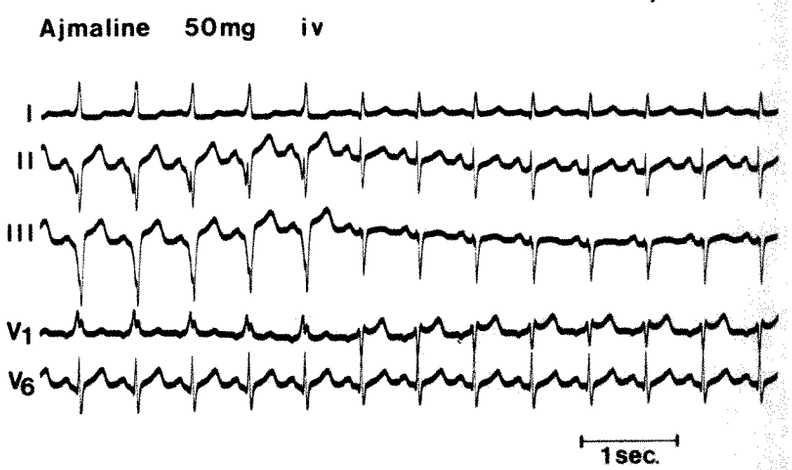

FIGURE 1. Creation of complete atrioventricular block in the accessory pathway by injecting 50 mg of ajmaline intravenously (IV) in a patient with a paraseptally located left-sided accessory pathway. Leads I, II, III, V_1 and V_6 were recorded simultaneously. Note that block in the accessory pathway develops suddenly (disappearance of delta wave and widening of QRS complex).

3 minute period. During and after the injection, leads I, II, III, V_1, V_5 and V_6 were simultaneously and continuously recorded. If no block in the accessory pathway occurred, recording of the electrocardiogram was stopped 15 minutes after termination of the ajmaline injection.

2. Twenty-four hours later, after informed consent was obtained, a programmed electric stimulation study was performed, using methods previously described.[10] The duration of the effective refractory period of the accessory pathway in the A-V direction was determined with the single test stimulus method during atrial pacing. At least three different basic cycle lengths were used. The effective refractory period of the accessory pathway in the A-V direction was defined as the shortest atrial premature stimulus interval showing A-V conduction over the accessory pathway from the atrial stimulation site closest to the atrial end of the accessory pathway.

In 18 patients 50 mg of ajmaline was again given during the programmed electric stimulation study and its effect on the duration of the anterograde effective refractory period of the accessory pathway determined using similar atrial stimulation sites, basic pacing cycle lengths and test stimulus intervals. All data were statistically analyzed using the paired *t* test.

Results

Relation between effect of ajmaline and duration of the effective refractory period of the accessory pathway (Fig. 1 and Table I): Ajmaline, in a dose of 50 mg given intravenously over a 3 minute period, caused complete anterograde block in the accessory pathway in 32 of the 59 patients studied. The block developed suddenly in 20 patients, and after a short episode of 2:1 block in the accessory pathway in 12 patients. Its duration ranged from 12 to 35 minutes. In the other 27 patients, especially in the presence of left-sided preexcitation, the contribution to ventricular excitation over the accessory pathway lessened, but preexcitation clearly persisted after administration of ajmaline (Fig. 2). Determination of the duration of the effective re-

* ≤270 msec in seven patients.
† >270 msec in one patient.
AP = accessory pathway; ERP = effective refractory period.

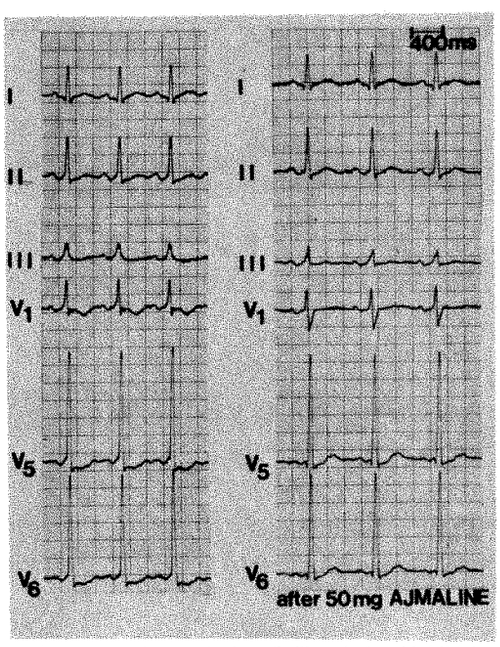

FIGURE 2. Electrocardiogram before **(left)** and after **(right)** intravenous administration of 50 mg of ajmaline in a patient with a left laterally located accessory pathway. Conduction over the accessory pathway persists, although the contribution to ventricular excitation over the accessory pathway diminishes. This phenomenon was also observed in other patients independent of the location of the accessory pathway, suggesting slowing in conduction over the accessory pathway and the adjoining ventricular myocardium after administration of ajmaline. ms = milliseconds.

fractory period of the accessory pathway in the anterograde direction 24 hours after ajmaline revealed a duration of 230 to 520 ms (mean 327 ± 70) among patients who had manifested complete anterograde block in the accessory pathway after ajmaline. In seven patients the duration was equal to or less than 270 ms. In patients in whom anterograde block did not develop after ajmaline, the duration of the effective refractory period of the accessory pathway in the anterograde direction ranged from 170 to 290 ms (mean 233 ± 28). In only one patient was the duration greater than 270 ms (290 ms). The difference between the mean duration of the effective refractory period of the accessory pathway in the anterograde direction between patients with and without anterograde block in the accessory pathway after ajmaline was statistically highly significant ($p < 0.0001$).

Reproducibility of results: In 18 patients 50 mg of ajmaline was again given intravenously over a 3 minute period during the stimulation study performed 24 hours after the ajmaline test. Complete anterograde block in the accessory pathway developed in 10 patients. These patients had also shown the same phenomenon 24 hours earlier. None of the eight patients in whom anterograde block did not develop after ajmaline was given during the stimulation study had shown anterograde block after injection of ajmaline 24 hours earlier. In four of these eight patients A-V conduction over the accessory pathway was present before and after ajmaline administration up to the effective refractory period of the atrium. Ajmaline produced a 10 to 20 ms lengthening of the effective refractory period of the atrium in these patients. In the remaining four patients the effective refractory period of the atrium was shorter than that of the accessory pathway; in these patients the effective refractory period of the atrium lengthened by 0, 10, 20 and 20 ms, and the effective refractory period of the accessory pathway by 20, 10, 30 and 40 ms, respectively. The effect of ajmaline on anterograde conduction over the accessory pathway was determined by the duration of the effective refractory period of the accessory pathway in the anterograde direction and not by the location of this pathway (Table II).

Side effects: Seven patients complained of a warm feeling in their face during the ajmaline injection. A visible flush developed in four of them. Another patient felt dizzy during and for 6 minutes after ajmaline administration.

Discussion

Ajmaline, a reserpine derivative, has been shown to prolong the effective refractory period of the accessory pathway in patients with the Wolff-Parkinson-White syndrome.[11,12] The effect is short-lived. In a previous study we found no residual effect of 50 mg of ajmaline on the accessory pathway 45 minutes after the drug was given intravenously.[12] During this investigation complete anterograde block in the accessory pathway lasted maximally 35 minutes after termination of ajmaline administration.

Clinical applications of the ajmaline test: Our data indicate that 50 mg of ajmaline given intravenously over a 3 minute period is a very useful method for identifying patients with the Wolff-Parkinson-White syndrome in whom the accessory pathway has a short refractory period in the anterograde direction. If no anterograde block in the accessory pathway develops after ajmaline administration, a short (less than 270 ms) duration of the effective refractory period of the accessory pathway in the anterograde direction is very likely. Gallagher et al.[9] recently observed that their patients with the Wolff-Parkinson-White syndrome and documented ventricular fibrillation had a refractory period of the accessory pathway of less than 250 ms, thus suggesting that the finding of a short refractory period of the accessory pathway can be of help in identifying patients at risk of sudden death if atrial fibrillation supervenes.

We found a relation between the effect of ajmaline and the initial duration of the anterograde refractory period of the accessory pathway. This relation was also noted by Chiale et al.,[13] and we have observed the same relation in several other drugs in patients with the Wolff-Parkinson-White syndrome.[14]

All of our patients received ajmaline intravenously in a dose of 50 mg irrespective of body weight. Because ajmaline can also be used in small children, a more practical dosage might be 1 mg/kg body weight up to a maximum of 70 mg.

We encountered no problems when using the ajmaline test in our patients. However, because complete anterograde block of the normal A-V pathway may be

present in the patient with an accessory A-V connection[15,16] the procedure should be performed under well controlled hospital conditions.

In the asymptomatic patient in whom anterograde block in the accessory pathway cannot be provoked with ajmaline our present policy is to determine the duration of the effective refractory period of the accessory pathway in the anterograde direction with programmed electric stimulation. This procedure is followed by determination of the ventricular rate during induced atrial fibrillation.

Application to prophylactic drug therapy: Administration of prophylactic drug therapy in the asymptomatic patient with the Wolff-Parkinson-White syndrome and a short refractory period of the accessory pathway in the anterograde direction is complicated by two considerations: (1) Only modest prolongation of the duration of the effective refractory period of the accessory pathway can be attained using commercially available drugs in such patients,[14] and (2) these drugs have a high incidence rate of side effects. Our current policy is to accumulate data on the natural history of the asymptomatic patient with a short duration of the refractory period of the accessory pathway. We believe that these data are required before a decision can be made on the advisability of life-long antiarrhythmic therapy versus surgical interruption of the accessory pathway.

Birmingham, Alabama

Employment and income status of 96 patients randomized into the Alabama portion of the National Cooperative Unstable Angina Study were evaluated before the patients' admission to the study and in 1977. All patients had at least 12 months of follow-up study (mean 38 months). The ratio of patients fully employed at the time of follow-up to those fully employed at entry into the study (baseline) was 0.68 for medically treated patients, 0.53 for surgically treated patients and 0.53 for patients in whom medical therapy failed and who later underwent operation. The changes in annual family income were +$1,111 for medical patients, −$2,447 for surgical and +$875 for those later undergoing surgery. Regression analysis revealed that nonwork income, initial work status, initial income, severity of angina while the patient was in the unstable angina study and the procedural variable (that is, persistent medical, early surgical or late surgical treatment) were associated with return to full-time employment. Changes in family income were related to change in work status, the procedural variable, the patient's education, initial work status, the spouse's income, occurrence of a myocardial infarction after entry into the unstable angina study, duration of angina before entry into the unstable angina study, marital status and sex. Patients who underwent initial surgery had the largest reduction in family income, related to the change in nonworking status at the time of follow-up interview.

In 1977, more than 70,000 coronary arterial bypass graft operations were performed at an estimated cost of $12,500 each. Total national costs of the operation alone in that year probably approached $1 billion.[1] These large costs have generated considerable debate over the results and benefits of the coronary bypass grafting procedure. In examining the costs and benefits of any medical procedure, an important initial step is to quantify the costs. Several investigators have reported estimates of the cost of the bypass operation, and a multidisciplinary group at the University of Alabama in Birmingham Medical Center recently reported[2] on the actual costs of medical and surgical treatment for patients entered into the Alabama portion of the National Cooperative Unstable Angina Study. In that study, for the 85 patients followed up for 2 years, the mean inpatient charges were $6,226 for 26 medically treated patients, $10,416 for 41 surgically treated patients and $20,059 for 18 patients who failed to adequately respond to medical therapy and later required surgical therapy. Differences between the groups were statistically significant ($p < 0.001$).

It is logical next to examine the relative benefits of the two treatment modes. It is generally accepted that bypass surgery improves exercise

performance and reduces the symptoms of angina pectoris. Part of the current debate about treatment modality revolves around social and economic factors. One important measure of the outcome of medical or surgical treatment modes is improved "quality of life," but this measure does not lend itself readily to quantitative analysis. A more easily examined aspect of the patient's life is the ability to be employed and thus to function independently. Additionally, family income is often considered to represent an approximation of the quality of life attainable. This paper reports on these two measures, that is, changes in employment status and changes in family income in patients with unstable angina pectoris who were treated medically or surgically as part of a prospective randomized clinical trial.

Methods

Patient groups: One hundred six patients from the University of Alabama in Birmingham portion of the National Heart, Lung, and Blood Institute's prospective randomized study of unstable angina (National Cooperative Unstable Angina Study) formed the patient group for the analysis. The protocol of the randomized study has been described in detail elsewhere.[3,4] Unstable angina pectoris was defined as a history of the recent onset of effort angina or a changing pattern of effort angina or angina at rest. These categories were not mutually exclusive. The patient must have generated enough concern in his or her physician to be admitted to a coronary care unit for observation. The patient must have had transient electrocardiographic changes with pain, no evidence of a new myocardial infarction in the electrocardiogram and no diagnostic rise in serum enzyme indicators of acute myocardial infarction during the stay in the hospital. Other requirements for patients in the trial were that all be under 70 years of age, that they had not experienced a myocardial infarction within 3 months of admission into the study and that they be in a state of health, except for coronary artery disease, consistent with a further life expectancy of at least 5 years.

Once the foregoing clinical criteria were satisfied and a diagnosis of unstable angina pectoris was made, informed consent was obtained and selective coronary arteriography and left ventriculography were undertaken. To be included in the clinical trial, a patient must have had one or more lesions of the coronary arteries judged to reduce the diameter of the vessels by at least 70 percent. The distal coronary circulation had to be of adequate size to accept a vascular graft. Left ventricular function was determined with left ventriculography; an ejection fraction greater than 30 percent and an end-diastolic volume less than 125 ml/m^2 body surface area were required for inclusion in the study. At the time of initial evaluation, patients with marked left ventricular dysfunction were excluded from the trial because assignment to medical treatment was considered obligatory. Surgical treatment was recommended if a patient had a severe obstructive lesion of the left main coronary artery (greater than 50 percent reduction of luminal diameter), and these patients were also excluded from the study. Medically treated patients who later required surgical therapy did so because of continued severe disabling stable angina pectoris or recurrent unstable angina pectoris that, in the opinion of the patient and physician, was altering the patient's life-style significantly and was therefore judged unacceptable.

Follow-up: Data on clinical variables were taken from the patient's medical records. Detailed data on work status and income changes were obtained from telephone, home or clinic interviews in the summer and fall of 1977. Ninety-six of the original 106 patients were interviewed. By the time of the interview, five patients had died, and five other patients were not available for clinical follow-up study. An examination of the characteristics of these 10 patients reveals that their omission does not bias the results of the study. The interview provided a cross-sectional evaluation of income and employment changes. At the time of the interview, patients had been entered into the study for 1 to 5 1/2 years (mean = 37.6 months, standard deviation = 13.4).

Of the 106 patients included in this study, 55 were allocated to medical therapy and 51 to surgical therapy. This paper focuses only on the 96 patients who responded to the follow-up interview in 1977. By that time, there were three groups of patients: 28 patients who remained on medical therapy throughout the study, 47 patients initially allocated to surgical therapy, and 21 patients who were initially allocated to medical therapy but subsequently required bypass surgery. In randomized clinical trials of heart disease the occurrence of patients in whom medical therapy fails is persistent.[3–6] Thus, it is important to examine this group of patients separately.

Analysis of data: The presentation of data is divided into a descriptive portion and an analytical portion. The descriptive portion first compares the three groups of patients by a variety of clinical and demographic variables. The remainder of the descriptive analysis compares changes in work status, income status and sources of income among the three groups of patients. Differences among the three groups were assessed using the F statistic from analysis of variance, whereas the difference between any two groups was assessed with the t statistic. The multivariate analytical portion assessed the factors that led to return to work as well as those that led to changes in income. Separate multiple regression analyses were used to examine return to work and income changes. Initially, a large array of clinical, demographic and social variables were analyzed, as well as treatment procedures. Subsequent analyses included only the most important variables in each of the regression equations. These refined regression equations are presented in the Results section. In the regression analysis the coefficient indicates magnitude of the relation and the direction of its effect. The beta value indicates the relative strength of the relation.

Results

Clinical variables of three patient groups: Table I compares the demographic and clinical characteristics of the persistent medical, surgical and late surgical groups. There are no statistically significant differences among the three groups for the following characteristics: age, percent female, mean years of education, number of years since the onset of angina, the occurrence of myocardial infarction during the study and mean number of coronary vessels diseased. The mean age of the patients was 53.8 years. Approximately 6 percent of the patients were women and the average level of education attained was graduation from high school. The average time since onset of angina was 3.1 years, and approximately 16 percent of the patients had one or more myocardial infarctions during the study. The groups differed with respect to the percent married and greatest severity of angina during the study as determined by the New York Heart Association classification for functional capacity.[7] All patients in the persistent medical group were married and more than 90 percent

TABLE II

Comparison of Full-Time Employment Status for Three Treatment Groups

Characteristics	Therapy: Persistent Medical (no. = 28)	Surgical (no. = 47)	Late Surgical (no. = 21)
Employment 3 months before entry into study (baseline)	78.6%	85.1%	85.0%
Employment at time of interview	53.6%	44.7%	45.0%
Ratio of employment after to employment before*	0.68	0.53	0.53

* Significant ($p < 0.01$).

of the surgically treated patients were married, whereas only slightly more than 75 percent of the late surgical group were married. The greatest severity of angina was found in the late surgical group, followed by those in the persistent medical and then the surgical group. The low incidence of severe angina in the initial surgical group reflects the relief of symptoms of angina pectoris afforded by the surgical procedure, whereas the high incidence of severe angina in the late surgical group reflects the high level of anginal symptoms prior to the decision to operate.

Employment status: A comparison of full-time employment status 3 months before entry into the study with employment status at the time of the interview is shown in Table II. Seventy-nine percent of the persistent medical group, 85 percent of the surgical group and 85 percent of the late surgical group were employed 3 months before entry into the study. At the time of the interview (1 to 5 1/2 years after entry) 54 percent of the medical, 45 percent of the surgical and 45 percent of the late surgical group were employed. In both periods these differences are not statistically significant. A ratio of percent employed at the time of the interview to percent employed 3 months before entry into the study is 0.68 for the persistent medical group and 0.53 for both the surgical and late surgical groups. This difference between the persistent medical group and both the initial surgical and late surgical groups was statistically significant ($p < 0.01$).

Family income: Table III compares reported gross family income 3 months before entry into the study with that at the time of the interview. There was no statistically significant difference between the incomes of the three groups 3 months before entry into the study and at the time of the interview. Patients in both the persistent medical group and the late surgical group reported gains in income from baseline to the time of interview ($1,111 and $875, respectively), whereas the surgical group had a reduction in income ($2,447). These changes in income among each of the three groups were significantly different from each other. The loss in earnings of the initial surgical group was to be expected because fewer patients in this group returned to work. When one adjusts the initial income for the reduction in buying power caused by inflation, all three groups of patients experienced a loss in real income. The mean loss was $3,662 for the persistent medical group, $6,700 for the surgical group and $3,679 for the late surgical group.

Table IV presents sources of income. About 65 percent of patients in the medical and late surgical groups had income sources of personal earnings compared with 51 percent for patients in the initial surgery group. Spouse's earnings reflect the finding that spouses of surgically treated patients worked the least, followed by spouses of patients in the late surgical and then the persistent medical group. However, the surgical group had the highest proportion of persons receiving pensions. Seventy-one percent of patients in the persistent medical group and approximately 50 percent of those in the surgical and late surgical groups receive income from other sources (money from relatives, loans, welfare payments, sale of property or earnings from stocks, bonds or savings). None of these differences were statistically significant.

Factors that affect return to work: Multiple regression analysis was performed on these factors. For the purposes of this analysis, only people who returned to work full time were considered employed. Also, patients who were retired before entry into the study and patients over age 60 years were excluded from the regression analysis, leaving 22 patients in the persistent medical group, 40 in the initial surgical group and 17 in the late surgical group. A series of stepwise regression analyses were performed with a large number of variables. Table V presents a best-fit regression analysis in which each variable was a significant predictor of return

TABLE III

Comparison of Family Income 3 Months Prior to Entry Into Study, at Time of Interview, and Change in Income Between Two Points of Time, for Three Treatment Groups

	Therapy		
	Persistent Medical (no. = 27)*	Surgical (no. 47)	Late Surgical (no. = 20)*
Mean family income 3 months before entry into study	$19,537 ± 17,948	$17,500 ± 14,891	$17,875 ± 15,288
Mean family income at time of interview	$20,648 ± 17,821	$15,053 ± 15,053	$18,750 ± 17,177
Change in income†	$+1,111 ± 7,217	$−2,447 ± 5,121	$+875 ± 8,163
Change in income adjusted for inflation†	$−3,662 ± 9,012	$−6,700 ± 7,074	$−3,679 ± 9,104

* One persistent medical patient and one late surgical patient refused to tell the interviewer their incomes.
† Significant ($p < 0.05$).

to full-time employment. Earlier regression equations included a large number of variables that were not significant. Among these nonsignificant variables were sex, age, education, number of years the patient had had angina, total number of coronary vessels diseased, and the occurrence of myocardial infarction after admission to the study.

The significant predictors of return to full-time employment are listed in order of importance. These predictors were: nonwork income at the time of the interview, work status 3 months before entry into the study, the procedural variable (that is, presence in the persistent medical group versus presence in the initial surgical or the late surgical group), and the greatest severity of angina since admission to the study. The most important of these predictors is nonwork income, which includes income from workman's compensation, unemployment insurance, welfare payments and pensions. The negative coefficient on this variable indicates that patients who were currently receiving nonwork income were less likely to be working at the time of the interview. If patients were working 3 months before entry into the study, they were more likely to be working at the time of the interview. Patients with higher family incomes before entry into the study were less likely to return to work. The coefficient of the procedural variable indicates, as does Table II, that patients in the persistent medical group were more likely to return to work than were patients who underwent surgery. Patients with more severe angina were less likely to return to work. Together, these variables explained 44 percent of the variance in return to full-time employment.

Factors affecting change in family income: Table VI presents the results of stepwise multiple regression analyses of the change in family income between the time 3 months before entry into the study and the time of the interview. Initially, a large array of demographic and clinical characteristics were included in the analysis. Unlike the regression analysis concerning return to full-time employment, this analysis excluded only patients who were retired before entry into the study; this left 24 patients in the persistent medical group, 44 patients in the initial surgical group and 19 patients in the late surgical group. Age at the time of interview was included in the regression analysis but was not a significant predictor.

Significant variables listed in order of importance were change in the patient's work status, the procedural variable (that is, initial allocation to surgical therapy versus medical therapy), mean years of education,

TABLE IV

Sources of Income at Time of Interview for Three Treatment Groups (Percent of Group Having the Source of Income)*†

	Therapy		
Sources	Persistent Medical (no. = 28)	Surgical (no. = 47)	Late Surgical (no. = 20)
Personal earnings	64.3 ± 48.8	51.1 ± 50.5	65.0 ± 48.9
Spouse's earnings	50.0 ± 50.9	36.2 ± 48.6	40.0 ± 50.3
Pensions	53.6 ± 50.8	59.6 ± 49.6	50.0 ± 51.3
Additional sources‡	71.4 ± 46.0	46.8 ± 50.0	55.0 ± 51.3

* One patient in the late surgical group would not provide sources of income.
† None of the variables are significant ($p < 0.05$).
‡ Additional sources include money from relatives, loans, welfare, sale of property, income from stocks or bonds and savings.

TABLE V

Stepwise Regression Analysis on Full-Time Employment at Time of Interview (79 patients)

† Significant (p <0.01).

working before entry into the study, spouse's income, the occurrence of one or more myocardial infarctions during the study, the number of years since the onset of angina, marital status and sex. If a patient's work status went from that of working 3 months before entry into the study to not working at the time of the interview, family income decreased $5,940. Patients who initially underwent surgery had a mean reduction in income of $2,684. Mean years of education were negatively related to change in income. Patients working before entry into the study and continuing to work at the time of interview had a positive change in income of $3,459. Families in which the patient's spouse was working at the time of the interview had an increase in income of $1,835. This variable becomes insignificant when martial status enters the regression because of multicollinearity. Patients who had one or more myocardial infarctions after entering the study had an unexpected positive change in income. Patients who had angina pectoris longer also had a positive change in income. The family incomes of married patients increased by $4,565. As indicated earlier, this variable is correlated with income from the spouse's employment, but the two variables have separate and distinct effects. The family income of female patients increased $5,427. However, as reported in the previous regression analysis, sex was not a significant predictor of return to full-time employment. Together these variables explained 32 percent of the change in family income. The significance of other variables was masked by their collinearity with the variables already in the equation. Alternative specifications of the equation cause reported variables to be replaced with other variables with less explanatory ability.

Discussion

Although there have been many studies of the return to work after a myocardial infarction[8–12] and others on return to work after coronary arterial bypass grafting or valvular surgery,[13–16] there appears to be only one published study comparing return to work among patients undergoing medical versus surgical therapy for coronary artery disease. Hammermeister et al.[17] examined employment characteristics of patients in a coronary angiography registry having cardiac catheterization or surgery in Seattle, Washington. Work status 3 months before catheterization or surgery was clearly the major variable predictive of continued employment 12 months later, regardless of whether the patients were treated medically or surgically. More than 83 percent (872 of 1,047) of patients working 3 months before catheterization or surgery continued to work at 12 months, whereas only 12 percent (36 of 307) of patients not working for the 3 month period before surgery or catheterization returned to work after treatment. Hammermeister et al. concluded that surgical therapy was not more effective than medical therapy in maintaining full-time employment in this registry of patients after catheterization. The major difference in the Seattle investigation and the patient group under examination at the University of Alabama in Birmingham is that the Seattle study examined all patients receiving medical or surgical treatment as part of the Seattle Heart Watch Registry, whereas the Birmingham study is a prospective investigation examining patients randomly assigned to medical or surgical therapy as part of a clinical trial.

Return to work after surgery: The results of our study indicate that patients who are successfully managed on medical therapy for unstable angina pectoris return to full-time employment at a significantly higher rate than do patients who undergo bypass surgery (both initially and late). This contradicts several earlier studies examining the return to work only among surgically treated patients, which found that the operation led to an increase in employment.[15,16] A detailed analysis of this phenomenon indicated that patients who have income from sources other than their own work or the work of their spouses (nonwork income) are least likely to return to full-time employment, regardless of the work status of the spouse. This study supports the findings of Barnes et al.[13] and Hammermeister et al.[17] in that patients who were working before entry into the study were more likely to return to full-time employ-

ment. However, a new and distinct finding is that patients who were making higher incomes were less likely to return to work. This result contradicts the prevalent notion that patients with high status, high paying jobs are likely to return to work after treatment for heart disease. Finally, as expected, patients with more severe angina pectoris are less likely to return to full-time employment.

Several factors may be hypothesized to explain why surgically treated patients return to work at a rate substantially lower than that of medically treated patients. The length of time preparing for surgery, the operation itself, and the recovery period may cause patients to seek early retirement, or the time required for the surgical procedure and recovery may cause patients to become unaccustomed to working. Pain from the operation, fright and possibly the fact that it is easier for surgically treated patients to become eligible for disability compensation, plus the attitudes of employers and associates toward patients who have had major surgical procedures, may also influence return to work.[18]

Family income after surgery: A comparison of family income 3 months before entry into the study and at the time of the interview indicated that patients who underwent initial surgery had the largest reduction in income, whether measured by actual income or income adjusted for inflation. Patients in the persistent medical group and the late surgical group experienced similar changes in actual income and in incomes adjusted for inflation. One reason for this similarity of changes in income in these two groups, despite the difference in return to full-time employment, is that approximately 65 percent of both groups continued to have income from personal earnings. For patients in the late surgical group, this was due to a higher rate of part-time employment than that of the other groups.

As expected, the most important explanatory variable in the regression analysis concerning the change in income during the study was a change in status from working 3 months before entry in the study to nonworking at the time of interview. The regression analysis confirmed the result that surgically treated patients had a significant decrease in income by comparison with the other groups when the other variables were held constant. The negative coefficient on the education variable again reflects the finding that patients from higher status groups did not return to full-time employment, and this event led to a decline in income for that subgroup.

Married patients had positive changes in income due to the effect of the spouse's income upon family income. Similarly, female patients experienced positive changes in family income, probably due to continued employment of their spouses. Surprisingly, families of patients who had had one or more myocardial infarctions while in the study had a positive change in income. Further analysis revealed that the work activity of the families of these patients was more likely to have increased because of the patient's heart disease; this finding may account for the higher family income. The increase in income among patients with a longer history of angina may be a result of their having previously adjusted their work and earnings to their heart disease.

Implications: This study is the first to examine in detail the return to work and changes in income among patients with unstable angina pectoris in a prospective randomized clinical trial. Patients who received only medical treatment were more likely to return to full-time employment than were comparable patients who initially underwent cardiac bypass surgery or who later required such surgery. Previous studies have compared the two procedures through examination of changes in longevity, relief of anginal pain and exercise performance. This study complements these efforts by assessing more completely the relative benefits of the two procedures through examining the patient's return to full-time employment and changes in family income. The procedural variable indicates that patients who initially underwent bypass surgery had the greatest decrease in family income, and these patients were the least likely to return to full-time employment. Patients who were successfully managed on medical therapy were most likely to return to full-time employment.

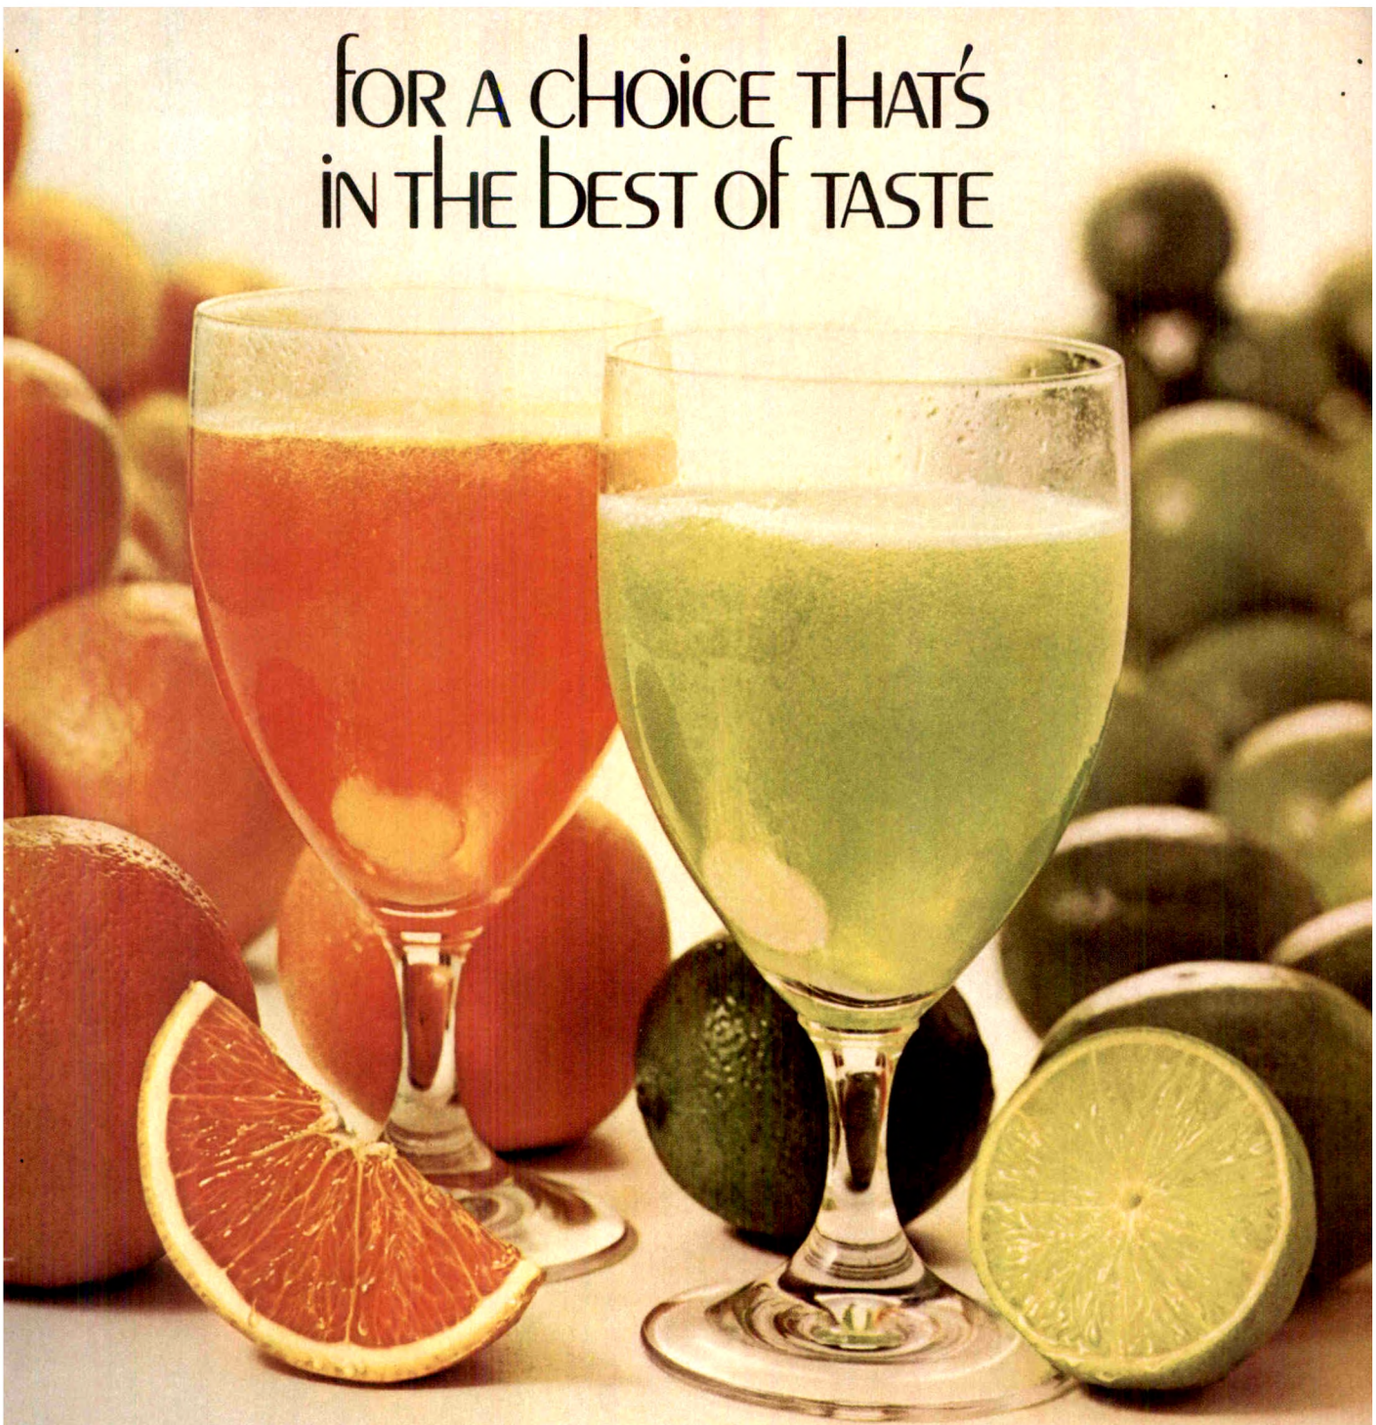
FOR A CHOICE THAT'S IN THE BEST OF TASTE



K-LYTE®

Each effervescent tablet in solution supplies 25 mEq potassium as bicarbonate and citrate

Orange and Lime Flavors
The best of taste for over a decade

K-LYTE® DS

Each effervescent tablet in solution supplies 50 mEq potassium as bicarbonate and citrate

Orange and Lime Flavors
Convenient once-a-day dosage

Prescribing Considerations

Indications: K-LYTE DS and K-LYTE are oral potassium supplements for therapy or prophylaxis of potassium deficiency. They are particularly useful when thiazide diuretics, corticosteroids, or severe vomiting and diarrhea cause excessive excretory potassium losses; and when dietary potassium is low. Carefully monitored, K-LYTE DS and K-LYTE may also be useful for potassium replacement where digitalis intoxication results in cardiac arrhythmias.

Contraindications: Impaired renal function with oliguria or azotemia; Addison's disease; hyperkalemia from any cause.

Warnings and Precautions: Since the amount of potassium deficiency may be difficult to determine accurately, supplements should be administered with caution, and dosages adjusted to the requirements of the individual patient. Potassium intoxication rarely occurs in patients with normal kidney function. Symptoms of potassium intoxication are variable. They include listlessness, mental confusion, and tingling of the extremities. Frequent checks of the clinical status of the patient, ECG, and serum potassium level are desirable. In established hypokalemia, attention should also be directed toward other potential electrolyte disturbances. Potassium supplements should be given cautiously to digitalized patients and such patients should be monitored by ECG for cardiac irregularities. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, **patients should be carefully directed to dissolve each dose completely in the stated amount of water.**

Adverse Reactions: Nausea, vomiting, diarrhea, and abdominal discomfort may occur with the use of potassium salts.

Dosage and Administration: Adults: 1 K-LYTE DS tablet (50 mEq potassium) completely dissolved in 6 to 8 ounces of cold or ice water, 1 to 2 times daily; 1 K-LYTE tablet (25 mEq potassium) completely dissolved in 3 to 4 ounces of cold or ice water, 2 to 4 times daily. **NOTE: It is suggested that K-LYTE DS and K-LYTE be taken with meals and sipped slowly over a 5 to 10 minute period.**

How Supplied: K-LYTE DS effervescent tablets (orange or lime flavors) are available in cartons of 30 and 100. K-LYTE effervescent tablets (orange or lime flavors) are available in cartons of 30 and 250. All tablets are individually foil wrapped.

THE NEW LOOK IN A-V SEQUENTIAL

CYBERLITH™ IV

PACING

The first A-V sequential pacemaker system to totally utilize the original CyberLith programming flexibility and reliability.

Compact and light-weight, the CyberLith IV A-V sequential pacemaker (model 259-01) is designed to accomodate your patient's long-term pacing requirements.

A-V sequential (DVI) pacing can increase cardiac output to enhance the treatment of heart failure and sick sinus syndrome. This pacing mode can also be used to suppress numerous arrhythmias.

The CyberLith IV is substantially smaller than any other A-V sequential pacemaker, weighing one-third less than its nearest competitor. It utilizes two reduced-size unipolar leads, and the resulting smaller catheter diameters facilitate passing these leads transvenously.

Multi-programmable, the CyberLith IV offers 15 rates, 15 pulse width settings and 7 sensitivity levels. The standard series 522 CyberLith Programmer permits selective noninvasive programming with all the necessary combinations.

When you make a choice for your patient's best interest, choose CyberLith IV.

Our business is life™

Intermedics CyberLith IV—Brief Summary

INDICATIONS FOR USE: Implantable cardiac pulse generators may be indicated for long-term treatment of impulse formation or conduction disorders resulting in symptomatic bradyarrhythmias, tachyarrhythmias, and heart block unresponsive to drug therapy.

A-V sequential pacing is specifically indicated for treatment of conduction disorders which require restoration of both rate dnd atrio-ventricular synchrony. A-V sequential pacing is also indicated for patients with extensive myocardial infarction with A-V block and sinus bradycardia.

CONTRAINDICATIONS AND SIDE EFFECTS: There are no known contraindications to the use of pacemakers as a medical method for control of heart rate. Body rejection phenomena, local tissue reaction or skin necrosis, muscle and nerve stimulation, embolism, and cardiac tamponade have been reported.

PRECAUTIONS: See the "Cautionary Notes" section of the Physician's Manual for the Intermedics cardiac pulse generator to be implanted. Discussion includes Possible Complications, Environmental Hazards (electrocautery, diathermy, defibrillation, microwave ovens, home appliances, and industrial and special environments), and Effects of Drugs on Cardiac Pacing.

NOTE: CyberLith IV is currently undergoing clinical evaluation.

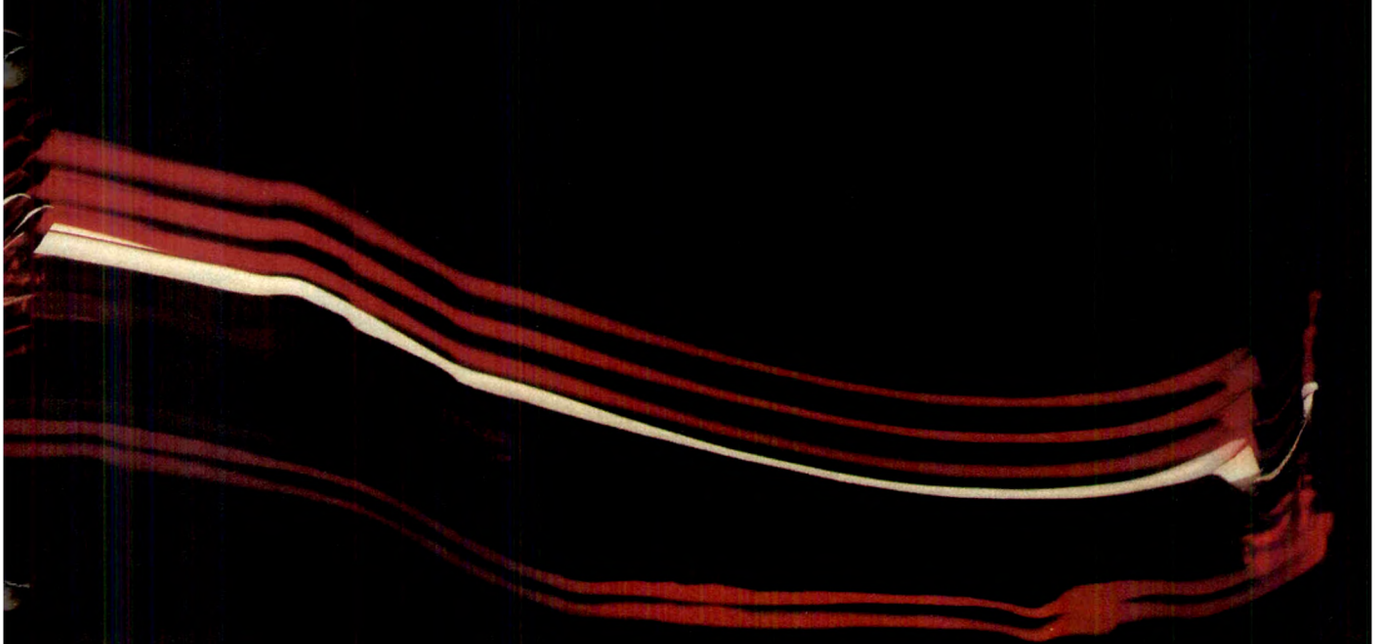
BRETYLOL®
(bretylium tosylate)

Unique antifibrillatory-antiarrhythmic effect
Unique mechanism of action
Unique safety: no cardiac depression



Bretylol® (bretylium tosylate), the unique new antifibrillatory-antiarrhythmic, provides lifesaving effects in the suppression of life-threatening ventricular arrhythmias unresponsive to lidocaine.

See last page of this advertisement for prescribing information.

New Breokinase® is highly purified human protein.

- Lower incidence of fever.[3,4]*
- Can be used effectively in patients with recent streptococcal infections or high titers of streptococcal antibodies.
- Less risk of allergic reactions than streptokinase.†

Now urokinase therapy at lower cost

- Offers substantial savings to both hospital and patient.
- Convenient. Ask your Breon representative for a list of depots. There is one near you.

*Febrile episodes occurred in about 2-3% of urokinase-treated patients. A causal relationship to urokinase has not been established.

†In vitro and intradermal tests gave no evidence of induced antibody formation. However, the possibility of serious allergic reactions occurring cannot be excluded. There have been rare reports of relatively mild allergic reactions such as bronchospasm and rash.

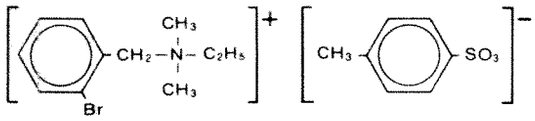
BRETYLOL bretylium tosylate

BRETYLOL INJECTION

FOR INTRAMUSCULAR OR INTRAVENOUS USE

DESCRIPTION

BRETYLOL (bretylium tosylate) is o-Bromobenzyl ethyldimethylammonium p-toluene sulfonate. The chemical structure is:



$C_{18}H_{24}BrNO_3S$ Mol. Wt. 414.39

BRETYLOL is a white, crystalline powder with an extremely bitter taste. It is freely soluble in water and alcohol. Each ml of sterile, pyrogen-free solution contains 50 mg bretylium tosylate in Water for Injection, USP. The pH is adjusted, when necessary, with dilute hydrochloric acid or sodium hydroxide. BRETYLOL contains no preservative.

CLINICAL PHARMACOLOGY

BRETYLOL (bretylium tosylate) is a bromobenzyl quaternary ammonium compound which selectively accumulates in sympathetic ganglia and their postganglionic adrenergic neurons where it inhibits norepinephrine release by depressing adrenergic nerve terminal excitability.

BRETYLOL also suppresses ventricular fibrillation and ventricular arrhythmias. The mechanisms of the antifibrillatory and antiarrhythmic actions of BRETYLOL are not established. In efforts to define these mechanisms, the following electrophysiologic actions of BRETYLOL have been demonstrated in animal experiments:

1. Increase in ventricular fibrillation threshold.

2. Increase in action potential duration and effective refractory period without changes in heart rate.

3. Little effect on the rate of rise or amplitude of the cardiac action potential (Phase 0) or in resting membrane potential (Phase 4) in normal myocardium. However, when cell injury slows the rate of rise, decreases amplitude, and lowers resting membrane potential, BRETYLOL restores these parameters toward normal.

4. Increase in impulse formation and spontaneous firing rate of pacemaker tissue as well as increased ventricular induction velocity.

The restoration of injured myocardial cell electrophysiology toward normal, as well as the increase of the action potential duration and effective refractory period without changing their ratio to each other, may be important factors in suppressing re-entry of aberrant impulses and decreasing induced dispersion of local excitable states.

BRETYLOL induces a chemical sympathectomy-like state which resembles a surgical sympathectomy. Catecholamine stores are not depleted by BRETYLOL, but catecholamine effects on the myocardium and on peripheral vascular resistance are often seen shortly after administration because BRETYLOL causes an early release of norepinephrine from the adrenergic postganglionic nerve terminals. Subsequently, BRETYLOL blocks the release of norepinephrine in response to neuron stimulation. Peripheral adrenergic blockade regularly causes orthostatic hypotension but has less effect on supine blood pressure. The relationship of adrenergic blockade to the antifibrillatory and antiarrhythmic actions of BRETYLOL is not clear. In a study in patients with frequent ventricular premature beats, peak plasma concentration of BRETYLOL and peak hypotensive effects were seen within one hour of intramuscular administration, presumably reflecting adrenergic neuronal blockade. However, suppression of premature ventricular beats was not maximal until 6-9 hours after dosing, when mean plasma concentration had declined to less than one-half of peak level. This suggests a slower mechanism, other than neuronal blockade, was involved in suppression of the arrhythmia. On the other hand, antifibrillatory effects can be seen within minutes of an intravenous injection, suggesting that the effect on the myocardium may occur quite rapidly.

BRETYLOL has a positive inotropic effect on the myocardium, but it is not yet certain whether this effect is direct or is mediated by catecholamine release.

BRETYLOL is eliminated intact by the kidneys. No metabolites have been identified following administration of BRETYLOL in man and laboratory animals. In man, approximately 70 to 80% of a ^{14}C-labelled intramuscular dose is excreted in the urine during the first 24 hours, with an additional 10% excreted over the next three days.

In various studies of BRETYLOL excretion, estimates of the terminal half-life have varied from about 5 to about 10 hours, with an even wider range in individual subjects (4 to 17 hours). Whether this represents true intrapatient variability or limitations of methodology remains to be determined.

Effect on Heart Rate: There is sometimes an initial small increase in heart rate when BRETYLOL is administered, but this is an inconsistent and transient occurrence.

Hemodynamic Effects: Following intravenous administration of 5 mg/kg of BRETYLOL to patients with acute myocardial infarction, there was a mild increase in arterial pressure, followed by a modest decrease, remaining within normal limits throughout. Pulmonary artery pressures, pulmonary capillary wedge pressure, right atrial pressure, cardiac index, stroke volume index, and stroke work index were not significantly changed. These hemodynamic effects were not correlated with antiarrhythmic activity.

Onset of Action: Suppression of ventricular fibrillation is rapid, usually occurring within minutes following intravenous administration. Suppression of ventricular tachycardia and other ventricular arrhythmias develops more slowly, usually 20 minutes to 2 hours after parenteral administration.

INDICATIONS

BRETYLOL is indicated in the treatment of life-threatening ventricular arrhythmias, principally ventricular fibrillation and ventricular tachycardia, that have failed to respond to adequate doses of a first-line antiarrhythmic agent, such as lidocaine or procainamide. At this time, BRETYLOL should not be considered a first-line antiarrhythmic agent.

Use of BRETYLOL should be limited to intensive care units, coronary care units or other facilities where equipment and personnel for constant monitoring of cardiac arrhythmias and blood pressure are available.

Following injection of BRETYLOL there may be a delay of 20 minutes to 2 hours in the onset of antiarrhythmic action, although it appears to act within minutes in ventricular fibrillation. The delay in effect appears to be longer after intramuscular than after intravenous injection.

CONTRAINDICATIONS

There are no contraindications to use in treatment of ventricular fibrillation or life-threatening refractory ventricular arrhythmias.

WARNINGS

1. Hypotension: Administration of BRETYLOL regularly results in postural hypotension, subjectively recognized by dizziness, light-headedness, vertigo or faintness. Some degree of hypotension is present in about 50% of patients while they are supine. Hypotension may occur at doses lower than those needed to suppress arrhythmias.

Patients should be kept in the supine position until tolerance to the hypotensive effect of BRETYLOL develops. Tolerance occurs unpredictably but may be present after several days.

Hypotension with supine systolic pressure greater than 75 mm Hg need not be treated unless there are associated symptoms. If supine systolic pressure falls below 75 mm Hg, an infusion of dopamine or norepinephrine may be used to raise blood pressure. When catecholamines are administered, a dilute solution should be employed and blood pressure monitored closely because the pressor effects of the catecholamines are enhanced by BRETYLOL. Volume expansion with blood or plasma and correction of dehydration should be carried out where appropriate.

2. Transient Hypertension and Increased Frequency of Arrhythmias: Due to the initial release of norepinephrine from adrenergic postganglionic nerve terminals by BRETYLOL, transient hypertension or increased frequency of premature ventricular contractions and other arrhythmias may occur in some patients.

3. Caution During Use with Digitalis Glycosides: The initial release of norepinephrine caused by BRETYLOL may aggravate digitalis toxicity. When a life-threatening cardiac arrhythmia occurs in a digitalized patient, BRETYLOL should be used only if the etiology of the arrhythmia does not appear to be digitalis toxicity and other antiarrhythmic drugs are not effective. Simultaneous initiation of therapy with digitalis glycosides and BRETYLOL should be avoided.

4. Patients with Fixed Cardiac Output: In patients with fixed cardiac output (i.e., severe aortic stenosis or severe pulmonary hypertension) BRETYLOL should be avoided since severe hypotension may result from a fall in peripheral resistance without a compensatory increase in cardiac output. If survival is threatened by the arrhythmia, BRETYLOL may be used but vasoconstrictive catecholamines should be given promptly if severe hypotension occurs.

USE IN PREGNANCY

The safety of BRETYLOL in human pregnancy has not been established. However, as the drug is intended for use only in life-threatening situations, it may be used in pregnant women when its benefits outweigh the potential risk to the fetus.

USE IN CHILDREN

The safety and efficacy of this drug in children has not been established. BRETYLOL has been administered to a limited number of pediatric patients, but such use has been inadequate to define fully proper dosage and limitations for use.

PRECAUTIONS

1. Dilution for Intravenous Use: BRETYLOL should be diluted (one part BRETYLOL with four parts of Dextrose Injection, USP or Sodium Chloride Injection, USP) prior to intravenous use. Rapid intravenous administration may cause severe nausea and vomiting. Therefore, the diluted solution should be infused over a period greater than 8 minutes. In treating existing ventricular fibrillation, BRETYLOL should be given as rapidly as possible and may be given without dilution.

2. Use Various Sites for Intramuscular Injection: When injected intramuscularly, not more than 5 ml should be given in a site, and injection sites should be varied since repeated intramuscular injection into the same site may cause atrophy and necrosis of muscle tissue, fibrosis, vascular degeneration and inflammatory changes.

3. Reduce Dosage in Impaired Renal Function: Since BRETYLOL is excreted principally via the kidney, dosage should be reduced in patients with impaired renal function.

ADVERSE REACTIONS

Hypotension and postural hypotension have been the most frequently reported adverse reactions (see Warnings section). Nausea and vomiting occurred in about three percent of patients, primarily when BRETYLOL was administered rapidly by the intravenous route (see Precautions section). Vertigo, dizziness, light-headedness and syncope, which sometimes accompanied postural hypotension, were reported in about 7 patients in 1000.

Bradycardia, increased frequency of premature ventricular contractions, transitory hypertension, initial increase in arrhythmias (see Warnings section), precipitation of anginal attacks, and sensation of substernal pressure have also been reported in a small number of patients, i.e., approximately 1-2 patients in 1000.

Renal dysfunction, diarrhea, abdominal pain, hiccups, erythematous macular rash, flushing, hyperthermia, confusion, paranoid psychosis, emotional lability, lethargy, generalized tenderness, anxiety, shortness of breath, diaphoresis, nasal stuffiness and mild conjunctivitis, have been reported in about 1 patient in 1000. The relationship of BRETYLOL administration to these reactions has not been clearly established.

DOSAGE AND ADMINISTRATION

BRETYLOL is to be used clinically only for treatment of life-threatening ventricular arrhythmias under constant electrocardiographic monitoring. Since there is a delay in onset of its antiarrhythmic action, BRETYLOL is not to be considered or used as a replacement for rapidly-acting antiarrhythmic agents currently in use. The clinical use of BRETYLOL is for short-term use only. Patients should either be kept supine during the course of BRETYLOL therapy or be closely observed for postural hypotension. The optimal dose schedule for parenteral administration of BRETYLOL has not been determined. There is comparatively little experience with dosages greater than 30 mg/kg/day although such doses have been used without apparent adverse effects. The following schedule is suggested:

A. For Immediately Life-threatening Ventricular Arrhythmia, as in Ventricular Fibrillation: Administer undiluted BRETYLOL at a dosage of 5 mg/kg of body weight by rapid intravenous injection. Other usual cardiopulmonary resuscitative procedures, including electrical cardioversion, should be employed prior to and following the injection in accordance with good medical practice. If ventricular fibrillation persists, the dosage may be increased to 10 mg/kg and repeated at 15 to 30 minute intervals until a total dose of not more than 30 mg/kg of body weight has been given. For maintenance dosage, see below.

B. Other Ventricular Arrhythmias:

1. Intravenous Use: *BRETYLOL must be diluted as follows before intravenous administration.* Using aseptic technique, dilute contents of one BRETYLOL ampul (10 ml containing 500 mg bretylium tosylate) to a minimum of 50 ml with Dextrose Injection, USP or Sodium Chloride Injection, USP.

Administer the diluted solution at a dosage of 5 to 10 mg BRETYLOL per kg of body weight by intravenous infusion over a period greater than 8 minutes. More rapid infusion may cause nausea and vomiting. A second dose may be given in 1 to 2 hours if the arrhythmia persists.

2. For Intramuscular Injection: *(Do not dilute BRETYLOL prior to intramuscular injection.)* Inject 5 to 10 mg BRETYLOL per kg of body weight. Dosage may be repeated in 1 to 2 hours if the arrhythmia persists. Thereafter maintain with same dosage every 6 to 8 hours.

Intramuscular injection should not be made directly into or near a major nerve, and the site of injection should be varied on repeated injection.

C. Maintenance Dosage: The diluted BRETYLOL solution may be administered by intermittent bolus infusion or by constant infusion.

1. Intermittent Infusion: Infuse the diluted solution at a dosage of 5 to 10 mg BRETYLOL per kg body weight, over a period greater than 8 minutes, every 6 hours. More rapid infusion may cause nausea and vomiting.

2. Constant Infusion: Infuse the diluted solution at a dosage of 1 to 2 mg BRETYLOL per minute.

Dosage of BRETYLOL should be reduced and discontinued in 3 to 5 days under electrocardiographic monitoring. Other appropriate antiarrhythmic agents should be substituted, if indicated.

HOW SUPPLIED

NDC 0094-0012-10: 10 ml ampul containing 500 mg bretylium tosylate in Water for Injection, USP, pH adjusted, when necessary, with dilute hydrochloric acid or sodium hydroxide. Sterile, pyrogen-free.

A Subsidiary of American Hospital Supply Corporation

Doctor: Before prescribing or administering Breokinase® (urokinase for injection) please read the following product information.

BREOKINASE®

(urokinase) for injection

Breokinase (urokinase for injection) should be used only by physicians with adequate experience in the management of thrombotic disease in hospitals where necessary clinical and laboratory monitoring can be performed (see Warnings, Precautions and Dosage and Administration).

The physician should carefully assess the overall clinical status and history of the patient before beginning urokinase treatment. Urokinase produces more profound changes in hemostasis and a greater frequency of bleeding than heparin or oral coumarin anticoagulant therapy. Bleeding when it occurs is more severe and more difficult to manage. Such factors as patient's age, physical condition, and underlying bleeding tendency (as described under Warnings and Precautions) should be taken into consideration when the potential risk of serious hemorrhage is weighed against the potential benefits of urokinase treatment.

Indications

Breokinase is indicated for the thrombolytic treatment of:

—acute massive pulmonary embolism, defined as obstruction or significant filling defects involving two or more lobar pulmonary arteries or an equivalent amount of emboli in other vessels, as seen on pulmonary arteriography;

—pulmonary embolism accompanied by unstable hemodynamics, i.e., inability to maintain blood pressure without supportive measures.

The diagnosis of pulmonary embolism should be confirmed by objective means, preferably pulmonary arteriography.

Urokinase treatment should be started as soon as possible after diagnosis of pulmonary embolism, but no later than five days after onset. Under these circumstances, angiographic and hemodynamic measurements and perfusion lung scans demonstrate a more rapid improvement during the first 24 hours after initiation of therapy than with heparin therapy. However, it has not been established that urokinase treatment decreases morbidity or mortality compared to heparin therapy alone.

Contraindications

Thrombolytic therapy increases the risk of bleeding. The risk of hemorrhage in the conditions listed below should be weighed carefully against the anticipated benefits of urokinase therapy in each patient. The benefits and risks associated with urokinase therapy should be compared to the benefits and risks associated with other forms of treatment.

1. Surgical procedures within preceding ten days (including liver or kidney biopsy, lumbar puncture, thoracentesis, paracentesis, extensive or multiple cutdowns).
2. Intraarterial diagnostic procedure within ten days.
3. Ulcerative wound.
4. Recent trauma with possibility of internal injuries.
5. Visceral or intracranial malignancy.
6. Pregnancy and the first ten days post-partum.
7. Actively bleeding lesion of the gastrointestinal or genitourinary tract, or a condition with significant potential for bleeding (including ulcerative colitis, diverticulitis).
8. Severe hypertension.
9. Acute or chronic hepatic or renal insufficiency.
10. Uncontrolled hypocoagulable state (including coagulation factor deficiency, thrombocytopenia, spontaneous fibrinolysis, any purpuric or hemorrhagic disorder).
11. Chronic pulmonary disease with cavitation, e.g., tuberculosis.
12. Subacute bacterial endocarditis or rheumatic valvular disease.
13. Recent cerebral embolism, thrombosis or hemorrhage (within at least two months) to avoid risk of bleeding into infarcted cerebral tissue.
14. Any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to locate or control.

Warnings

Bleeding: Activation of the fibrinolytic system with urokinase causes a more profound change in the hemostatic status of the patient than does anticoagulant therapy with heparin or coumarin agents. The objective of urokinase therapy is the production of sufficient amounts of plasmin to lyse intravascular deposits of fibrin; however, fibrin deposits which provide hemostasis, for example at sites of needle punctures, will also undergo lysis, and bleeding from such sites may occur. The possibility of bruising or hematoma formation, especially with intramuscular injections, is substantial during thrombolytic therapy. Unnecessary clinical or diagnostic procedures should be avoided. It is important that close attention be paid to this section and the Contraindications section in order to minimize the risk of bleeding.

Intramuscular injections should be avoided during urokinase therapy, as with heparin therapy, because of the high risk of hematoma formation. Bleeding may occur at sites of recent invasive procedures. Therefore, arterial punctures must be avoided before as well as during treatment with urokinase. If arterial puncture is *absolutely* necessary, the radial or brachial artery should be used and the femoral artery must be avoided. Arterial puncture should be performed with great care by an experienced physician and pressure should be applied for at least 15 minutes. This should be followed by the application of a pressure dressing, and the puncture site should be checked frequently for evidence of bleeding.

Venipunctures should also be performed as carefully and infrequently as possible. If bleeding from an invasive site occurs during urokinase infusion, but is not severe, treatment may be continued with close clinical observation. Local pressure and other measures should be initiated immediately.

Spontaneous internal bleeding that is not accessible for the application of pressure may also occur. The risk of spontaneous bleeding is greater in patients with pre-existing hemostatic abnormalities, including patients whose histories are suggestive of prior bleeding problems whether or not there are demonstrable abnormalities in platelet count, prothrombin time, partial thromboplastin time, or bleeding time. The relative risks and benefits of urokinase treatment must be carefully assessed in such patients before initiating treatment.

Plasmin degrades fibrinogen, Factor V, Factor VIII, and other proteins in addition to fibrin. The products of plasmin degradation of fibrinogen and fibrin (FDP/fdp) possess an anticoagulant effect which may make bleeding difficult to control.

If serious spontaneous bleeding occurs, the infusion of urokinase should be terminated immediately, and treatment instituted as described under Adverse Reactions.

Risk of Cerebral Embolism

Urokinase treatment of patients with atrial fibrillation or other conditions which predispose to cerebral embolism may be hazardous because of the risk of bleeding into the infarcted cerebral area.

Use of Anticoagulants

Concurrent use of anticoagulants with urokinase may be hazardous and is not recommended. Before beginning urokinase infusion in patients being treated with heparin, the effects of heparin should be allowed to decrease, as evidenced by a thrombin time of less than twice normal or an activated partial thromboplastin time (APTT) of less than one and one-half times normal. Similarly, heparin should be withheld for four hours following urokinase therapy unless the prothrombin time is in the normal range.

Rethrombosis has been observed after completion of urokinase treatment. In order to minimize this risk, administration of intravenous heparin followed by oral anticoagulant therapy is considered a necessary adjunct following urokinase therapy (see Dosage and Administration).

Use in Pregnancy

See Contraindications.

Use in Children

Safety and effectiveness of urokinase therapy in children have not been established; therefore, treatment of such patients is not recommended.

Precautions

Drug Interactions

Drugs that may alter platelet function, e.g., aspirin, indomethacin, and phenylbutazone should be avoided during urokinase treatment. The interaction of BREOKINASE with other drugs has not been studied.

Laboratory Monitoring

In patients who have received heparin, the thrombin time or APTT should be measured prior to starting urokinase. (See Warnings.) Similarly, the prothrombin time should be monitored during and following urokinase therapy prior to instituting heparin. (See Dosage and Administration.) During urokinase administration, the levels of fibrinogen, plasminogen, Factor V, and Factor VIII are usually substantially decreased, and the level of fibrin and fibrinogen degradation products (FDP/fdp) is increased. Reduced fibrinogen and increased FDP/fdp result in a prolongation of the prothrombin time. Changes in these tests serve as confirmation of the existence of a lytic state. There are no data to indicate that alteration of dosage is required on the basis of these tests, although as a general rule the prothrombin time should not be allowed to increase above 30 seconds.

Urokinase infusion should be terminated immediately if serious bleeding occurs.

Adverse Reactions

Careful observance of the contraindications, warnings, and precautions to the use of urokinase is essential to minimize the incidence and severity of adverse effects.

Bleeding

Incidence

In controlled clinical trials of streptokinase and urokinase, severe bleeding (requiring a transfusion of greater than two units of blood) was seen in 4% of streptokinase patients and 6% of patients receiving urokinase. Several fatalities due to cerebral hemorrhage have occurred during urokinase therapy.

Spontaneous bleeding of a less severe degree has been observed during urokinase treatment at about twice the frequency as that occurring during heparin therapy. Oozing of blood from sites of skin puncture is frequent; therefore, all invasive procedures, especially arterial punctures and intramuscular injections, should be avoided and intravenous punctures kept to a minimum before and during treatment with urokinase.

A moderate decrease in hematocrit not accompanied by clinically detectable bleeding was observed in about 20% of patients treated with urokinase.

Management of Severe Bleeding

Urokinase therapy must be discontinued if serious bleeding occurs. Packed red cells are indicated for large blood loss. Plasma volume expanders (other than Dextran) may be used to replace blood volume deficit. Whole blood may also be used if it alone is available. The use of aminocaproic acid (ACA, AMICAR®) in humans as an antidote for urokinase has not been documented, but its use may be considered if the hemorrhage is unresponsive to blood replacement (see Warnings).

Allergic Reactions:

Urokinase is a protein of human origin, and *in vitro* as well as intradermal tests in humans gave no evidence of induced antibody formation. However, the possibility of serious allergic reactions (including anaphylaxis) occurring during its use cannot be excluded. There have been rare reports of relatively mild allergic reactions, e.g., bronchospasm and skin rash.

Fever:

Febrile episodes occurred in about 2-3% of urokinase-treated patients. A causal relationship to urokinase has not been established. Symptomatic treatment with acetaminophen rather that aspirin is usually sufficient.

Dosage and Administration

Preparation

Reconstitute each vial of Breokinase by aseptically adding 8.0 ml of Sterile Water for Injection, U.S.P. (It is important that *only* Sterile Water for Injection, U.S.P., *without* preservatives, be used. Bacteriostatic Water for Injection or other diluents should not be used.) Swirl gently to avoid foaming. **Do Not Shake.** Because Breokinase contains no preservatives, it should not be reconstituted until immediately before using. Any unused portion of the reconstituted material should be discarded.

Each ml of reconstituted Breokinase contains 31,250 C.T.A. Units of urokinase activity.

Dosing

Breokinase is Intended for Intravenous Infusion Only

Urokinase treatment should be begun as soon as possible after the occurrence of pulmonary embolism, and no later than five days after onset. A priming or loading dose of 2000 C.T.A. Units/lb (4400 C.T.A. Units/kg) of reconstituted Breokinase is given over a period of ten minutes. This is followed by a continuous infusion of 2000 C.T.A. Units/lb/hr (4400 C.T.A. Units/kg/hr) for 12 hours.

A constant infusion pump independent of all other intravenous systems should be used. Do not expose reconstituted solution to excessive heat, such as high intensity lights, during administration.

Anticoagulation Following Breokinase Treatment

At the end of Breokinase infusion, treatment with heparin by continuous intravenous infusion followed by oral anticoagulant therapy is recommended to minimize rethrombosis. Heparin treatment should begin 4 hours after Breokinase infusion, or sooner if the prothrombin time has returned to normal. See manufacturer's prescribing information for proper use of heparin.

How Supplied

Breokinase is supplied as a sterile lyophilized preparation. Each vial contains 250,000 C.T.A. Units of urokinase activity and approximately 0.9 millimols sodium phosphates. The vials should be stored at or below 4° C.

Hypertrophic Cardiomyopathy

Recent Observations Regarding the Specificity of Three Hallmarks of the Disease: Asymmetric Septal Hypertrophy, Septal Disorganization and Systolic Anterior Motion of the Anterior Mitral Leaflet

BARRY J. MARON, MD, FACC
STEPHEN E. EPSTEIN, MD, FACC

Bethesda, Maryland

Neither asymmetric septal hypertrophy (ASH), marked cell disorganization in the ventricular septum nor systolic anterior motion of the anterior mitral leaflet (SAM) is pathognomonic of hypertrophic cardiomyopathy. However, each is uncommonly found in patients with other cardiac disorders and is therefore a highly specific hallmark of hypertrophic cardiomyopathy. Disproportionate septal thickening does occur in about 10 percent of older children and adults with various acquired or congenital heart diseases. In these patients it usually appears to be secondary to the underlying hemodynamic state. However, disproportionate septal thickening is the usual finding in the developing embryonic and fetal heart and it is relatively common (prevalence rate about 25 percent) in normal neonates and infants with congenital heart disease.

Likewise, although cell disorganization in the ventricular septum may occur with other cardiac malformations, extensive disorganization is present in about 90 percent of patients with hypertrophic cardiomyopathy and in only about 5 percent of patients with other cardiac diseases. Finally, systolic anterior motion of the anterior mitral leaflet is characteristic of those patients with hypertrophic cardiomyopathy who have obstruction to left ventricular outflow, and it rarely appears (prevalence rate about 3 percent) under basal conditions in other hemodynamic states or cardiac diseases. Hence, in analyses comprising over 1,600 patients the specificity of asymmetric septal hypertrophy, marked septal disorganization and systolic anterior motion of the anterior mitral leaflet was at least 90 percent (90, 93 and 97 percent, respectively). Furthermore, the sensitivity of extensive septal disorganization for hypertrophic cardiomyopathy was 90 percent.

The data currently available therefore suggest that the vast majority of patients fulfilling the basic anatomic criteria for hypertrophic cardiomyopathy (that is, a hypertrophied nondilated left ventricle in the absence of a cardiac or systemic disease that itself could produce left ventricular hypertrophy) have a distinct disease entity with diverse clinical manifestations. The majority of such patients appear to have a genetically transmitted disease, but it is not known precisely what proportion of these patients have phenotypically similar but etiologically separate disease entities.

From the Cardiology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received May 8, 1979; revised manuscript received August 3, 1979, accepted August 17, 1979.

It has been 20 years since the first systematic description of hypertrophic cardiomyopathy. In that initial report Teare[1] set the stage for the ensuing 2 decades of investigation by describing a disease in which the characteristic anatomic finding was an asymmetrically hypertrophied ventricular septum containing bizarrely arranged muscle cells. In the 1960's

Please see prescribing information on last page of this advertisement. It is important to pay close attention to WARNINGS and CONTRAINDICATIONS sections to minimize the risk of bleeding.

several investigators,[2–12] particularly those in Bethesda,[2–5] London[6–8] and Toronto,[9,10] defined many of the clinical, hemodynamic and pathologic features of hypertrophic cardiomyopathy. Their studies were largely confined to patients who manifested left ventricular outflow tract obstruction, and for this reason the disease bore several names that emphasized its obstructive nature: muscular subaortic stenosis, hypertrophic obstructive cardiomyopathy (HOCM) or idiopathic hypertrophic subaortic stenosis (IHSS).

In the late 1960's and early 1970's echocardiography was utilized to define two important features of hypertrophic cardiomyopathy. First, systolic anterior motion of the anterior mitral leaflet (SAM) was described in those patients with obstruction to left ventricular outflow.[13–16] Second, asymmetric septal hypertrophy (ASH) was identified as the characteristic anatomic abnormality of virtually all patients within the broad disease spectrum of hypertrophic cardiomyopathy, whether or not outflow obstruction was present.[17–20]

The observation by M mode echocardiography that, in patients with hypertrophic cardiomyopathy, ventricular septal thickness usually exceeded that of the posterior left ventricular free wall by a ratio of 1.3 or more[17,20] confirmed the anatomic observations made by others at necropsy.[21,22] Also, Teare's observation that the disproportionately thickened ventricular septum in hypertrophic cardiomyopathy contained large numbers of hypertrophied, bizarrely shaped and disorganized cardiac muscle cells was subsequently verified by several morphologic studies utilizing light and electron microscopy.[23–33]

Although it is now apparent that asymmetric septal hypertrophy, septal disorganization and systolic anterior motion of the anterior mitral leaflet cannot be regarded as pathognomonic hallmarks of hypertrophic cardiomyopathy, data recently accumulated indicate that these three abnormalities nevertheless are characteristic and highly specific features of patients with hypertrophic cardiomyopathy. Because of the importance of this subject it seems appropriate at this time to summarize our views regarding these most recent observations, which have helped extend the understanding of this intriguing disease.

Although ASH, septal disorganization and systolic anterior motion of the anterior mitral leaflet are important hallmarks of hypertrophic cardiomyopathy, they are by no means the only criteria used in making the diagnosis of this disease. However, this review is limited to a consideration of these three characteristic features of the disease and is not intended to be either a comprehensive analysis of all clinical and pathologic findings in hypertrophic cardiomyopathy or an inclusive guide to the diagnostic evaluation of patients with this complex disorder.

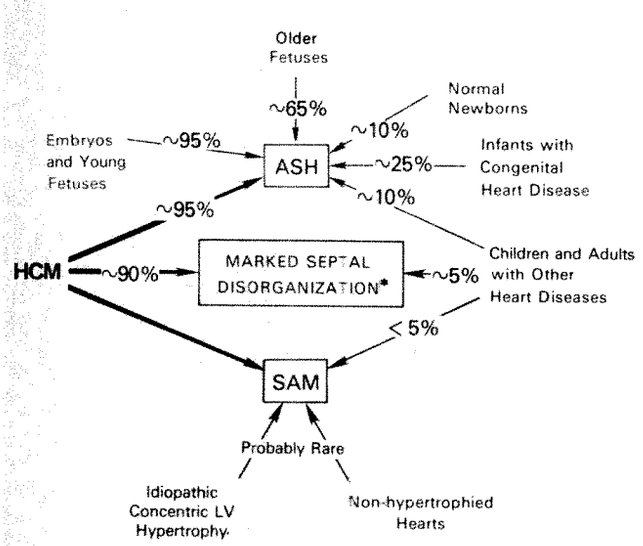

FIGURE 1. Occurrence of asymmetric septal hypertrophy (ASH), marked septal disorganization and systolic anterior motion of the anterior leaflet of the mitral valve (SAM) in normal cardiac development and in patients with acquired or congenital heart disease. * = involving 5 percent or more of the relevant parts of the tissue section. HCM = hypertrophic cardiomyopathy; LV = left ventricular.

Asymmetric Septal Hypertrophy*

Prevalence in other cardiac diseases: Despite the initial belief that asymmetric septal hypertrophy might be a pathognomonic marker of hypertrophic cardiomyopathy,[17] subsequent studies [34–50] showed that this was not the case (Fig. 1). During the past 3 years we have analyzed M mode echocardiograms and necropsy specimens from more than 900 patients who had either a normal heart or cardiac diseases other than hypertrophic cardiomyopathy in order to determine the prevalence of abnormal septal/free wall thickness ratios (1.3 or greater) in different cardiac states.[34–36,39,40] Analysis of ventricular wall thicknesses with echocardiography or at necropsy in 523 children or adults with various congenital or acquired heart diseases showed that about 10 percent had disproportionate thickening of the ventricular septum relative to the left ventricular free wall (Fig. 2); this thickening was apparently secondary to the underlying cardiac abnormality and not a manifestation of associated hypertrophic cardiomyopathy. Hence, although a septal/free wall ratio of 1.3 or greater is not pathognomonic of hypertrophic cardiomyopathy, the specificity (Table I) of an abnormal septal/free wall ratio for hypertrophic cardiomyopathy is extremely high (93 percent) (Table II).

The exact prevalence of disproportionate septal thickening in patients who had other heart diseases was related to the particular underlying cardiac disease and hemodynamic state (Fig. 3). Disproportionate septal thickening was most common (prevalence rate greater than 15 percent) in patients with lesions producing long-standing right ventricular hypertension,

* The terms asymmetric septal hypertrophy (ASH) and disproportionate septal thickening (DST) are used in this review to describe the same gross anatomic abnormality (a hypertrophied ventricular septum that is at least 1.3 times the thickness of the left ventricular free wall). However, the former implies the existence of a primary cardiomyopathy and the latter a secondary form of disproportionate ventricular septal thickening.

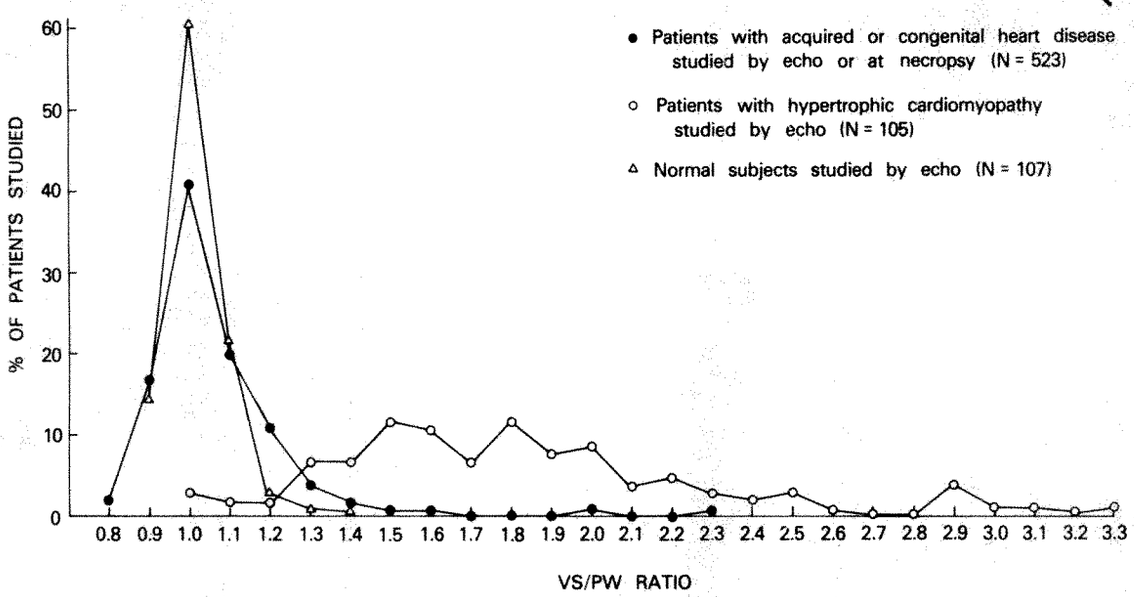

FIGURE 2. Distribution of ventricular septal to posterior left ventricular free wall thickness ratios (VS/PW) in 523 children and adults with various acquired or congenital heart diseases studied with echocardiography or at necropsy (**closed circles**), 105 consecutive patients with the clinical features of hypertrophic cardiomyopathy studied with echocardiography during 1979 (**open circles**) and 107 normal adult subjects studied with echocardiography (**triangles**). The frequency distribution curve for 523 patients with acquired or congenital heart disease is based on echocardiographic observations in 274 patients and on necropsy findings in 249 patients. The frequency distribution curves for echocardiographic and necropsy populations were similar and are therefore combined here. Seven patients with an abnormal septal free wall ratio were excluded from an original group of 530 children and adults with various acquired or congenital heart diseases[32,34–36] because coexistent genetically transmitted hypertrophic cardiomyopathy was identified.

such as pulmonary valve stenosis or primary pulmonary hypertension. It was less common (9 to 15 percent) in patients with Eisenmenger's syndrome, acquired aortic or both aortic and mitral valve disease, or coronary artery disease, and it was distinctly uncommon (less than 7 percent) in patients with isolated mitral valve disease or systemic hypertension (without associated coronary artery disease). In our experience, we have not yet observed disproportionate septal thickening in patients with uncomplicated left to right shunts (atrial or ventricular septal defect), dilated (congestive) cardiomyopathy or forms of left ventricular outflow obstruction other than hypertrophic cardiomyopathy.

In patients with cardiac lesions producing a predominant right ventricular overload, the prevalence of disproportionate septal thickening correlated directly with right ventricular systolic pressure. Disproportionate septal thickening was not present in patients with a right ventricular pressure of 40 mm Hg or less, but was present in 7 percent of patients with a pressure of 41 to 60 mm Hg and in 21 percent of patients with pressure of more than 60 mm Hg (Fig. 4). However, right ventricular hypertension is not the sole factor responsible for the genesis of disproportionate septal thickening. Indeed, the latter occurred in almost 10 percent

TABLE I

Glossary of Terms

$$\text{Specificity} = \text{Percent of negative results in patients without hypertrophic cardiomyopathy} = \frac{\text{True negative}}{\text{True negative} + \text{False positive}} \times 100$$

$$\text{Sensitivity} = \text{Percent of all patients with hypertrophic cardiomyopathy who manifest an abnormal test} = \frac{\text{True positive}}{\text{True positive} + \text{False negative}} \times 100$$

TABLE II

Specificity and Sensitivity of Three Hallmarks of Hypertrophic Cardiomyopathy Assessed With Echocardiography or at Necropsy in 1,664 Patients

	ASH	Extensive† Septal Disorganization	SAM
Sensitivity	*	90%	‡
Specificity	90%	93%	97%
Patients (n)	523	420	721

* It was not possible to calculate a meaningful figure for the sensitivity of ASH because its presence has been utilized at our institution as evidence for hypertrophic cardiomyopathy during the past 7 years.

† Involving 5 percent or more of the relevant areas of the tissue section.

‡ A figure for the sensitivity of marked SAM was not calculated because this abnormality is usually limited to only those patients with hypertrophic cardiomyopathy in whom obstruction to left ventricular outflow is present.

ASH = asymmetric septal hypertrophy (septal-free wall thickness ratio 1.3 or greater); SAM = systolic anterior motion of the anterior mitral leaflet (assessed with echocardiography).

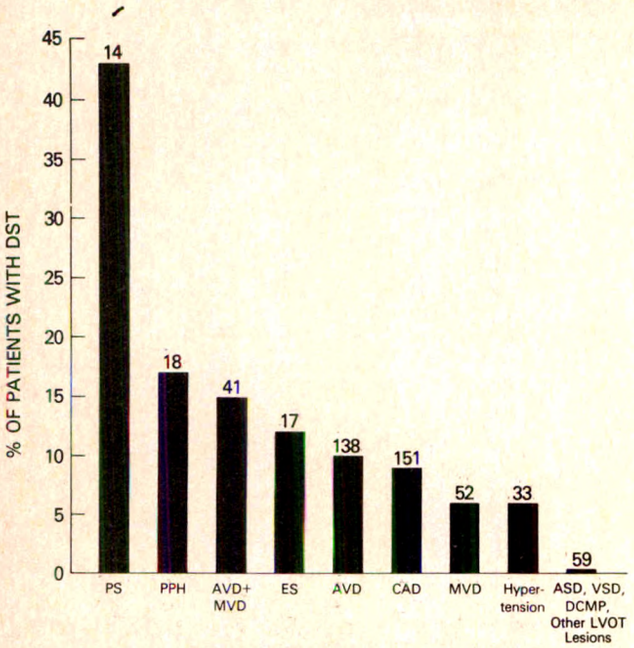

FIGURE 3. Prevalence of disproportionate septal thickening (DST) with respect to associated cardiac lesion. Each **bar** represents combined total of patients studied with echocardiography and at necropsy; the **numbers** at the top of bars denote patients studied in each subgroup. Seven patients with an abnormal septal/free wall ratio were excluded from an original group of 530 children and adults with various acquired or congenital heart diseases[32,34–36] because coexistent genetically transmitted hypertrophic cardiomyopathy was identified. ASD = atrial septal defect; AVD = aortic valve disease; CAD = coronary artery disease; DCMP = dilated (congestive) cardiomyopathy; ES = Eisenmenger syndrome; LVOT = left ventricular outflow tract obstruction; MVD = mitral valve disease; PPH = primary pulmonary hypertension; PS = pulmonary valve stenosis; VSD = ventricular septal defect.

(6 of 64) of our patients with normal right ventricular pressure and predominant left ventricular overload.

There are two other situations in which an abnormal septal/free wall thickness ratio may occur in a patient with acquired or congenital heart disease. First, transmural scarring with loss of muscle and marked thinning of the left ventricular free wall (Fig. 5) in the area through which the ultrasonic beam would pass during life may be present in patients with valvular or coronary heart disease[35,43,48,51] and occasionally may be the principal determinant of an abnormal septal/free wall ratio ("disproportionate thinning" of the left ventricular free wall).[35,43] Echocardiographic studies also have shown that some of the patients with clinically evident inferior myocardial infarction have an abnormal septal/free wall ratio usually due primarily to compensatory ventricular septal thickening.[43] Second, difficulty is frequently encountered in defining the right ventricular surface of the septum on echocardiography. Thus, echocardiographic overestimation of ventricular septal thickness may result from spurious incorporation of tricuspid valve structures into the measurement of septal thickness. The septal limb of the crista supraventricularis (Fig. 6) and right ventricular muscle bundles or trabeculae may also be mistaken for the right side of the septum, particularly in patients with severe right ventricular hypertension.

Distinguishing secondary disproportionate septal thickening from primary hypertrophic cardiomyopathy: Identification of an abnormal septal/free wall ratio on echocardiography in a patient with cardiac disease other than hypertrophic cardiomyopathy presents a diagnostic dilemma for the clinician. Does the patient have two diseases—an acquired or congenital heart malformation as well as genetically transmitted hypertrophic cardiomyopathy—or is the patient's abnormal septal/free wall ratio only secondary to the underlying cardiac malformation and not a manifestation of hypertrophic cardiomyopathy (Fig. 7)? This question has important practical implications. If genetically transmitted hypertrophic cardiomyopathy

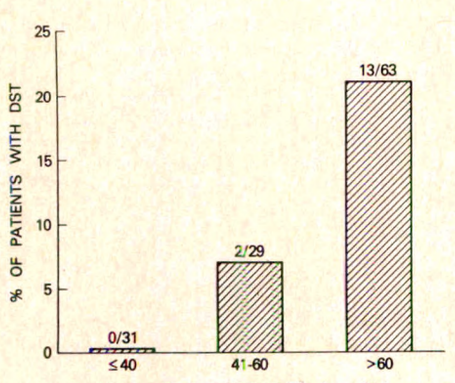

FIGURE 4. Relation between right ventricular (RV) systolic pressure and prevalence of disproportionate septal thickening (DST), shown for cardiac lesions producing predominant right ventricular overload. The greater prevalence of disproportionate septal thickening in patients with elevated right ventricular systolic pressure compared with those with normal pressures reached statistical significance ($p < 0.05$).

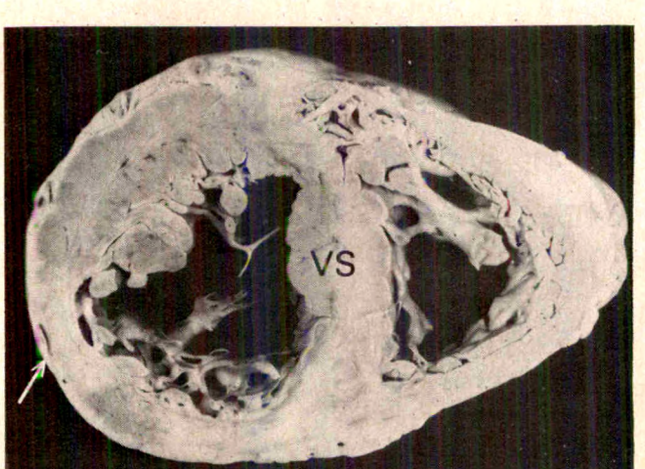

FIGURE 5. Heart of a patient with coronary artery disease. The abnormal septal/free wall ratio (2.0) is due primarily to marked scarring with loss of muscle (caused by a healed myocardial infarct) in the left ventricular free wall (**arrow**). This is the area of the free wall through which an ultrasonic beam would theoretically have passed during life. The ventricular septum (VS) shows moderate "compensatory" thickening and measures 20 mm; left ventricular free wall thickness in the area of scarring is 10 mm. Reproduced from Maron et al.[35] with permission of the American Heart Association Inc.

is present in a patient with another cardiac disease, the underlying cardiomyopathy may contribute independently to the patient's symptoms and clinical course. In contrast, secondary disproportionate septal thickening probably exerts no practical influence on the clinical course of the patient with acquired or congenital heart disease.

Unfortunately, we have not been able to discriminate reliably between these two possibilities simply by analysis of such echocardiographic measurements as septal/free wall ratio or absolute ventricular septal thickness. For example, although the vast majority of patients with secondary disproportionate septal thickening had a "borderline" septal/free wall ratio (1.3 or 1.4), 20 percent had a ratio of 1.5 or greater. Similarly, although most patients with secondary disproportionate septal thickening had relatively mild ventricular septal thickening (less than 20 mm), 15 percent had more marked thickening. Other workers[48] have suggested that patients with posterior ("inferior") left ventricular wall infarction and an abnormal septal/free wall ratio may be distinguished echocardiographically from patients with true hypertrophic cardiomyopathy by the minimal systolic thickening of the left ventricular free wall and diminished free wall excursion relative to that of the septum found in patients with prior infarction.

In our experience bedside examination has not proved a reliable means of determining, in a patient with an abnormal septal/free wall ratio associated with another cardiac or systemic disease, whether the septal thickening is secondary or is indicative of an associated primary cardiomyopathy (that is, hypertrophic cardiomyopathy). Rather we have found that the most practical method of making this distinction is echocardiographic study of closely related family members. It is our view[52] as well as that of other investigators[53] that in the vast majority of instances hypertrophic cardiomyopathy is genetically transmitted as an autosomal dominant trait with a high degree of penetrance. Thus, the probability is only about 3 percent that five first degree relatives of a patient with hypertrophic cardiomyopathy will each have a negative echocardiographic study. Hence, the absence of asymmetric septal hypertrophy in five or more first degree adult relatives of a patient with an abnormal septal/free wall ratio and acquired or congenital heart disease strongly suggests

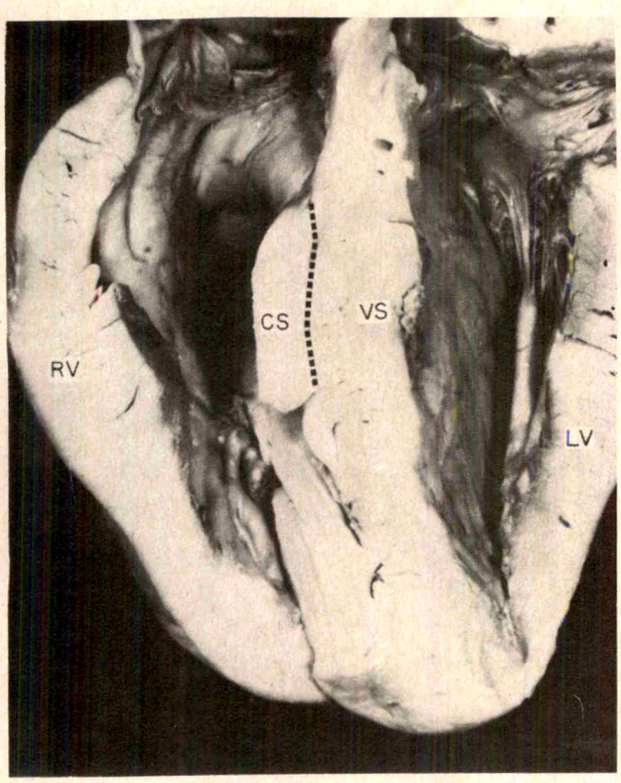

FIGURE 6. Heart of a 10 year old girl with primary pulmonary hypertension. The heart is sectioned in a plane parallel to the long axis of the left ventricle. The **broken line** indicates the probable point of division between the septal band of the crista supraventricularis (CS) and the true ventricular septum (VS). During life an ultrasonic beam would most likely have passed through both the hypertrophied crista supraventricularis and the ventricular septum. Because a boundary would not be distinguishable between these two structures, ventricular septal thickness would be considerably overestimated. LV = left ventricular free wall; RV = right ventricular wall.

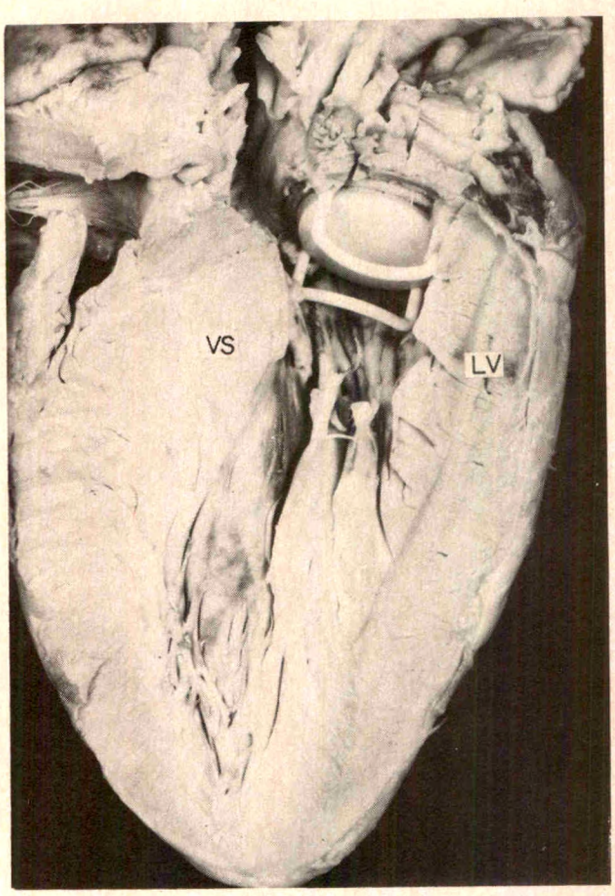

FIGURE 7. Longitudinally sectioned heart of a 43 year old woman with severe mitral regurgitation who died after mitral valve replacement. The ventricular septum (VS) is disporportionately thickened with respect to the left ventricular (LV) free wall. It was not possible to discern definitively whether the septal thickening in this patient was secondary to acquired mitral valve disease or was a manifestation of primary hypertrophic cardiomyopathy, because the patient's first degree relatives were not available for echocardiographic studies.

that the septal thickening present in the index case was not a manifestation of genetically transmitted disease. Conversely, the presence of an abnormal septal/free wall ratio in one or more relatives suggests the presence of a primary cardiomyopathy in the index case.

Hence, we used echocardiographic evaluation of family members in initially studying our series of older children and adults with acquired or congenital heart disease and an abnormal septal/free wall ratio. In addition, if the index patient died, sections of ventricular septum were analyzed at necropsy for the presence of marked disorganization of cardiac muscle cells (a highly specific and sensitive feature of hypertrophic cardiomyopathy[32]) (Tables I and II). By utilizing one or both of these methods we found that in the population studied an abnormal septal/free wall ratio was usually not a manifestation of genetically transmitted hypertrophic cardiomyopathy; that is, evidence of associated hypertrophic cardiomyopathy was present in only 7 of 55 patients with an abnormal ratio. Specifically, (1) in only 4 (15 percent) of 26 families studied with echocardiography (in which the index case had both an associated cardiac lesion and an abnormal septal/free wall ratio) did one or more first degree relatives also have asymmetric septal hypertrophy; (2) in just 3 (10 percent) of 29 other patients with an abnormal septal/free wall ratio was marked ventricular septal disorganization present at necropsy; and (3) the unimodal distribution curve of septal/free wall thickness ratios for the population of patients with acquired or congenital heart disease suggests that the abnormal ratios found in this group represent only the extreme end of a continuous spectrum and not a separate disease (Fig. 2). This distribution contrasts with the apparent bimodal distribution curve found in a population of first degree relatives of patients with hypertrophic cardiomyopathy (Fig. 8). The features of both primary hypertrophic cardiomyopathy and secondary disproportionate septal thickening are summarized in Table III.

Other reports have described the association of clinically evident hypertrophic cardiomyopathy or muscular subaortic obstruction with a heterogeneous assortment of congenital[54–65] or acquired[66–72] heart diseases, as well as diseases not usually associated with cardiac malformations.[73–82] However, in the majority of patients described in those studies the presence or absence of disproportionate ventricular septal thickening or genetic transmission of hypertrophic cardiomyopathy in family members was not documented, making it difficult to relate the findings of those studies to the concepts discussed here.

Disproportionate septal thickening in the normal developing and neonatal heart and in infants with congenital heart disease: Disproportionate septal thickening is also a characteristic feature of the developing human heart, particularly in the earliest stages of embryonic life.[45,83] In an analysis of 151 normal hearts at various stages of development (embryo, fetus and young infant),[83] we found that a septal/free wall ratio of 1.3 or greater was present in more than 90 percent of embryos and young fetuses. Disproportionate septal thickening was also present in 65 percent of older fetuses and 25 percent of live-born infants without congenital heart disease (only 12 percent of those over 2 weeks of age).

Disproportionate thickening of the septum was quite marked in young embryos, and a septal/free wall ratio

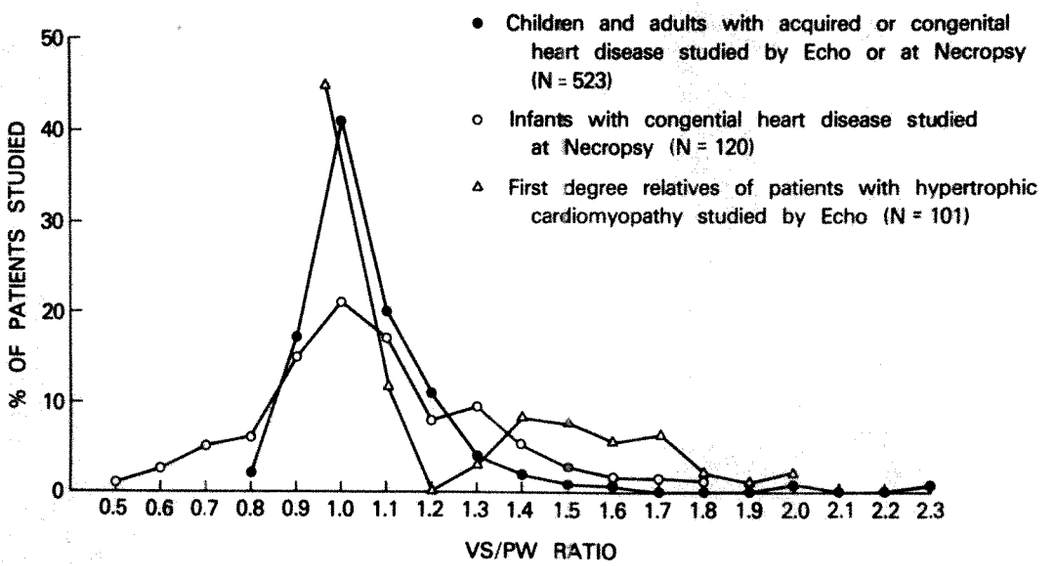

FIGURE 8. Distribution of ventricular septal to posterior left ventricular free wall thickness ratios (VS/PW) in 523 children and adults with various acquired and congenital heart diseases studied with echocardiography or at necropsy (**closed circles**), 101 first degree relatives of patients with hypertrophic cardiomyopathy studied with echocardiography (**triangles**) and 120 infants with congenital heart disease studied at necropsy (**open circles**). Seven patients with an abnormal septal/free wall ratio were excluded from an original group of 530 children and adults with acquired or congenital heart diseases,[32,34–36] and five patients were excluded from an original group of 125 infants with congenital heart disease[39] because coexistent genetically transmitted hypertrophic cardiomyopathy was identified.

TABLE III

Comparison of Features of Primary Hypertrophic Cardiomyopathy and Secondary Disproportionate Septal Thickening

	Abnormal VS/PW	Associated Cardiac Lesions	Evidence of Genetic Transmission: VS/PW ≥ 1.3 in 1° Relatives by Echo	Evidence of Genetic Transmission: Disorganized Cells in Septum	Subaortic Obstruction at Rest*
Hypertrophic cardiomyopathy (primary)	Present	Uncommon	Present	≥5%†	Common
Disproportionate septal thickening (secondary)	Present	Present	Absent	<5†	Uncommon

* Assessed either with cardiac catheterization or echocardiographic studies (that is, presence of systolic anterior motion of the anterior mitral leaflet).

† Percent area of the relevant parts of the tissue section that are occupied by disorganized cardiac muscle cells.[32]

VS/PW = ventricular septal to posterior left ventricular free wall thickness ratio.

of greater than 2.0 was a frequent finding in this group. However, during subsequent pre- and postnatal growth, septal/free wall thickness ratios gradually diminished in a curvilinear fashion and disproportionate septal thickening became progressively less common. This decrease in septal/free wall ratio appears to occur because the ventricular septum, which is markedly thicker than the left ventricular free wall in the earliest stages of development, increases in thickness at a slower rate than the left ventricular free wall during subsequent cardiac growth, particularly after birth (Fig. 9). Before birth, the rate of growth of the left ventricular free wall is 20 percent greater than that of the ventricular septum; after birth, it is 33 percent greater than that of the septum.

Because disproportionate thickening of the ventricular septum is a characteristic anatomic feature of both the normal developing heart[45,83] and the heart with hypertrophic cardiomyopathy, it is possible that asymmetric septal hypertrophy in patients with hypertrophic cardiomyopathy represents postnatal persistence of a normal anatomic feature of the embryonic heart. However, it is more likely that the development of asymmetric septal hypertrophy in patients with hypertrophic cardiomyopathy occurs by mechanisms independent of those intrinsic to normal cardiac development. Support for this hypothesis is provided by the absence of marked disorganization of ventricular septal architecture in the normal developing heart.[83] It is also possible that cell disorganization occurs at a later stage in the evolution of the disease and is not a necessary feature of hypertrophic cardiomyopathy at the time that asymmetric septal hypertrophy has already become evident.

Disproportionate septal thickening is also a common finding in infants with various congenital heart malformations other than hypertrophic cardiomyopathy[39,40] (Fig. 8). In a necropsy study of 120 such infants who died in the first 2 years of life (most of whom had malformations associated with right ventricular hypertension), 26 (22 percent) were found to have a septal/free wall thickness ratio of 1.3 or greater. Serial echocardiographic studies suggest that this disproportionate thickening of the septum present in infants with congenital heart disease (as well as in normal infants) is transient and usually disappears by age 2, primarily because continued thickening of the posterior left ventricular wall exceeds that of the ventricular septum.[46]

Utility of septal/free wall ratio in the diagnosis of hypertrophic cardiomyopathy: There has been some disagreement among investigators regarding the most appropriate septal/free wall ratio for identifying adult patients with hypertrophic cardiomyopathy. We have defined disproportionate ventricular septal thickening as a septal/free wall thickness ratio of 1.3 or greater.[17,20,34–36,39,40] Other investigators have advocated a ratio of 1.5 or 1.6 as being more specific.[18,19,84] Clearly, there is no single correct "cut point" for septal/free wall thickness ratio. As Figure 2 demonstrates,

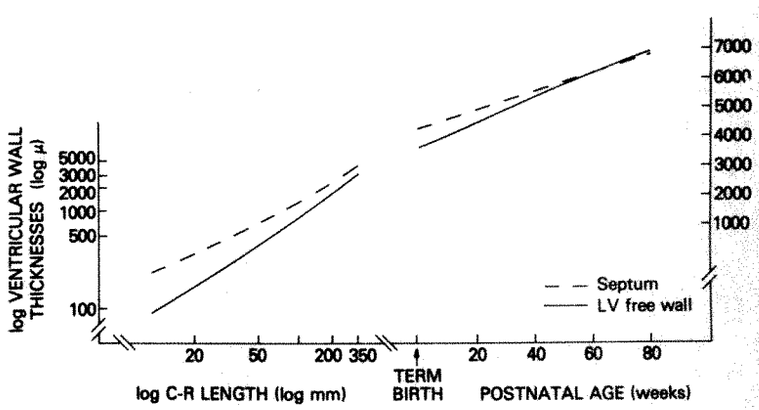

FIGURE 9. Changes in ventricular septal and left ventricular (LV) free wall thicknesses before and after birth in the developing normal human heart. C-R = crown-rump.

shifting the line to a higher ratio will increase specificity at the expense of decreasing sensitivity. Thus, although an occasional, presumably normal subject and a minority of patients with other acquired or congenital cardiac diseases may have a "borderline" septal/free wall thickness ratio of 1.3 or 1.4, approximately 15 percent of patients with typical hypertrophic cardiomyopathy will also have a ratio in this range and about 5 percent will even have a normal ratio of less than 1.3 (Fig. 2). Hence, just as a septal/free wall ratio of 1.3 or greater does not, in itself, confirm the diagnosis of hypertrophic cardiomyopathy, a ratio of less than 1.3 does not exclude the diagnosis of hypertrophic cardiomyopathy.

Similar problems arise if a ventricular septal thickness of 15 mm or greater (in addition to a septal/free wall ratio of 1.3 or greater) is required to establish the diagnosis of hypertrophic cardiomyopathy in an average-sized adult patient (it should be emphasized that absolute ventricular septal thickness is related to age and body surface area[85]). Such a requirement would minimize overdiagnosis resulting either from variation within the normal population or from inaccuracies inherent in measurements of wall thickness. Nevertheless, several of our patients with hypertrophic cardiomyopathy and asymmetric septal hypertrophy have had a septal thickness of 13 or 14 mm and occasionally such a patient has died suddenly and unexpectedly.[86] Hence, we do not believe it is appropriate to adhere rigidly to a particular lower diagnostic limit of septal thickness when evaluating a patient for possible hypertrophic cardiomyopathy.

The selection of 1.3 as the criterion for disproportionality between septal and free wall thicknesses emanates from necropsy[21] *and echocardiographic*[17] *studies performed primarily in adult patients,* and it was not specifically designed for application in infants with heart disease. Indeed, when septal/free wall ratios are calculated from absolute wall thickness values that are very small (as is the case in infants), minor differences in the thicknesses of ventricular septum and left ventricular free wall may yield calculated ratios considerably greater than unity and lead to a false positive diagnosis of hypertrophic cardiomyopathy. Hence, the thickness ratio of 1.3 or greater should not be applied routinely as the sole criterion for diagnosing hypertrophic cardiomyopathy in infants[28] or young children, particularly because an abnormal septal/free wall ratio is so common in normal neonates and infants with congenital heart diseases other than hypertrophic cardiomyopathy.[39,45,83] Also necessary for establishing the diagnosis of hypertrophic cardiomyopathy in such patients is (1) a ventricular septum that is clearly thicker than normal in absolute terms; (2) evidence of genetic transmission of asymmetric septal hypertrophy in first degree relatives, and (3) if necropsy evaluation is possible, marked disorganization of septal architecture.

Hypertrophic cardiomyopathy in infants must also be distinguished clinically from a transient nonfamilial condition that has recently been described in infants of diabetic mothers.[87–89] These latter infants characteristically manifest disproportionate septal thickening, systolic anterior motion of the anterior mitral leaflet (associated with a left ventricular outflow gradient) and symptoms and signs suggestive of congestive heart failure. Such infants of diabetic mothers, unlike those with "true" hypertrophic cardiomyopathy, usually show symptomatic improvement (spontaneously, with the termination of digitalis treatment, or with propranolol therapy), loss of outflow obstruction (and systolic anterior motion of the anterior mitral leaflet) and regression of septal hypertrophy within the first few months of life. This clinical entity is probably a manifestation of the generalized organomegaly present in infants of diabetic mothers rather than of a primary cardiomyopathic process.[89]

Discrepancies between detection of asymmetric septal hypertrophy on echocardiography and at necropsy: Problems in diagnosing hypertrophic cardiomyopathy frequently arise in the patient who was identified as having an abnormal septal/free wall thickness ratio during life, but whose septal thickness was not disproportionately greater than that of the posterior left ventricular wall at necropsy. In a comparative echocardiographic and necropsy study of nine patients with an abnormal septal/free wall ratio of 1.3 or greater during life, six had a ratio that was not diagnostic of disproportionate septal thickening at necropsy.[90] We found that these discrepancies could be explained in the following way. The echocardiographic measurements during life were made in diastole (as per convention), whereas the measurements at necropsy were made in hearts that appeared to be in the systolic phase of the cardiac cycle. When these patients were alive, the left ventricular free wall thickened considerably more than did the septum in systole, as determined with echocardiography, resulting in septal/free wall ratios in systole that were consistently smaller than those in diastole. However, the septal/free wall ratios calculated from systolic measurements corresponded closely to those obtained at necropsy.

The implication of these findings is that the diagnosis of hypertrophic cardiomyopathy cannot always be established by simple measurement of the relative thicknesses of ventricular septum and left ventricular free wall at necropsy. In these instances, the presence of a hypertrophied nondilated left ventricle (in the absence of other cardiac or systemic diseases that can produce left ventricular hypertrophy) should in itself lead to the presumptive diagnosis of hypertrophic cardiomyopathy.* Ancillary observations would also aid in establishing the diagnosis, including the typical clinical, hemodynamic and echocardiographic features of hypertrophic cardiomyopathy during life and a documented family history of hypertrophic cardiomyopathy. Of additional aid is the finding of a fibrous en-

* However, even this definition of hypertrophic cardiomyopathy has its occasional exceptions because certain patients with this disease who experience chronic, progressive congestive heart failure associated with transmural myocardial infarction (in the absence of significant atherosclerosis of the extramural coronary arteries) may actually show left ventricular dilatation.[91]

docardial plaque on the ventricular septum adjacent to a thickened anterior mitral leaflet, or marked disorganization of cardiac muscle cells in the ventricular septum.

Potential role of two-dimensional echocardiography in defining the distribution of myocardial hypertrophy in hypertrophic cardiomyopathy: Preliminary experience with wide angle two dimensional echocardiography suggests that this technique may be useful in defining the distribution of left ventricular hypertrophy in patients with hypertrophic cardiomyopathy[92-95] and in many instances may provide structural information not available from conventional M mode echocardiography alone. While the latter usually identifies the asymmetric nature of the cardiac hypertrophy in patients with hypertrophic cardiomyopathy (and, hence, the principal gross anatomic marker of the disease), it may not provide information about the true distribution of hypertrophy within the entire left ventricular wall. For example, in patients with hypertrophic cardiomyopathy, the M mode ultrasonic beam generally passes through the thickest portion of the left ventricular wall, the anterior ventricular septum, and also through the thinnest portion of the left ventricular wall, the posterior free wall. However, wide angle two dimensional echocardiography has demonstrated that the anterolateral left ventricular free wall (as well as the posterior portion of the ventricular septum) may also be markedly hypertrophied in these patients. Furthermore, wide angle two dimensional echocardiography has shown great variability in the distribution of ventricular septal hypertrophy; patients with hypertrophic cardiomyopathy may have hypertrophy principally either in the upper one third, the upper two thirds or the lower one third of the ventricular septum.[92]

Cell Disorganization in the Ventricular Septum

After publication of Teare's initial report,[1] several other investigators[23-33] observed a bizarre disorganized arrangement of cardiac muscle cells in the ventricular septum of patients who died of hypertrophic cardiomyopathy. However, as was the case with asymmetric septal hypertrophy, it soon became apparent that disorganized septal architecture was not a pathognomonic feature of hypertrophic cardiomyopathy (Fig. 1). Small areas of disorganization were described in the ventricular septum of some patients with various acquired or congenital heart diseases,[34-36,45,96] as well as in normal infants,[83] and infants who died suddenly without evidence of structural cardiac disease.[97]

Quantitative histologic method to determine extent of cell disorganization: Although these findings have led some investigators to question the usefulness of septal disorganization as a diagnostic marker of hypertrophic cardiomyopathy,[45,63,64,96] it was our impression that the distinction between disordered septal architecture occurring in hypertrophic cardiomyopathy or in other cardiac diseases depended primarily on the *extent* to which the disorganization was present. Hence, a quantitative histologic method was devised that permitted a more critical assessment of the relative area of septal myocardium occupied by disorganized cells.[32] In brief, hematoxylin-eosin stained tissue sections were photographed and the images were enlarged sufficient to occupy 30 by 40 inch (75 by 100 cm) positive prints; this enlargement resulted in an average magnification of about 5,000 times the original tissue section. A transparent cellulose overlay was then placed over the print and areas of myocardium occupied by disorganized cardiac muscle cells were demarcated on the overlay. Each area into which the tissue section had been divided was then quantitated by means of a video planimetry system.

In developing this quantitative method we found that septal disorganization was present more frequently and to a greater extent in tissue sections obtained perpendicular to the long axis of the left ventricle (that is, transverse plane), than in sections cut parallel to the long axis of the left ventricle. Hence, we have now quantitatively analyzed tissue sections obtained in the transverse plane at necropsy from 60 patients with hypertrophic cardiomyopathy and 360 control patients (including infants, children and adults with a variety of congenital or acquired heart diseases or normal hearts).[32,33] With this quantitative method, marked septal disorganization (involving 5 percent or more of the relevant areas of the tissue section) was found to be both a highly sensitive (90 percent) and specific (93 percent) histologic marker of hypertrophic cardiomyopathy (Tables I and II).

Septal disorganization was present in 95 percent of the patients with hypertrophic cardiomyopathy studied. Disorganization was extensive in these patients, involving 5 percent or more of the relevant areas of the tissue section in 90 percent of the patients, 25 percent or more of the tissue section in more than 50 percent of the patients and 50 percent or more in about 25 percent of the patients (Fig. 10). The mean area of ventricular septum disorganized was 31 percent in patients with hypertrophic cardiomyopathy.

In the control patients, septal disorganization was relatively uncommon, being present in about 20 percent of the 360 control patients studied, and it was usually quite limited in extent. In only 7 percent of the control patients studied did abnormally arranged cells occupy 5 percent or more of the tissue section and in only 1 percent did disorganized cells involve 25 percent or more of the section (Fig. 10). The mean area of ventricular septum disorganized was only about 1 percent in the control patients and, hence, substantially less than in patients with hypertrophic cardiomyopathy ($p < 0.001$). *Hence, it is not the presence, as such, of disorganized cardiac muscle cells in the ventricular septum that distinguishes patients with hypertrophic cardiomyopathy from patients with other heart diseases (or those with normal hearts), but rather the extent to which disorganization is present.*

We also found that marked septal disorganization linked patients within the broad clinical and pathologic spectrum of this disease; that is, disorganization was present and did not differ appreciably in extent in those

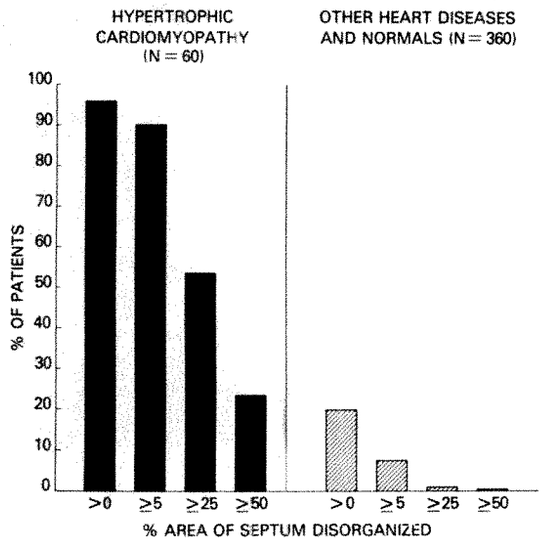

FIGURE 10. Percent area of ventricular septum occupied by disorganized cardiac muscle cells in 60 patients with hypertrophic cardiomyopathy and in 360 control patients.

patients either with or without symptoms before death, with asymmetric and symmetric (concentric) ventricular wall thickening at necropsy or with or without obstruction to left ventricular outflow. In addition, the presence or extent of septal disorganization was not related to absolute heart weight and, hence, cannot be considered simply a manifestation of marked cardiac hypertrophy.

Etiology of cardiac muscle cell disorganization: The origin of this cell disorganization is not definitively known. The quantitative histologic findings just cited suggest that extensive cell disorganization may be a primary derangement of septal architecture—that is, a morphologic manifestation of the underlying genetic defect known to be present in a large proportion of patients with hypertrophic cardiomyopathy. However, other investigators favor the theory that septal disorganization results secondarily from unique mechanical stresses to which the left ventricle in hypertrophic cardiomyopathy is exposed. In particular, Bulkley et al.[50] have recently proposed that septal disorganization in hypertrophic cardiomyopathy is due to a prolonged period of isometric contraction during mid and late ventricular systole. As support for this theory these investigators cited the presence of disorganized cardiac muscle cells in the small ventricular septum of infants who died of aortic or pulmonary valve atresia (with associated hypoplastic ventricular cavity), cardiac diseases in which prolonged isometric contraction may also occur during life. However, we have found no morphologic evidence to support this theory. Our quantitative histologic analysis of 33 infants with aortic or pulmonary atresia[33] showed that the extent of septal disorganization in these hearts was quite limited (mean area of ventricular septum disorganized about 2 percent), was significantly less than that in patients with hypertrophic cardiomyopathy (mean area of septum disorganized 31 percent; $p < 0.001$), and did not differ substantially from that found in a group of 91 infants with other congenital heart diseases associated with normal-sized or dilated ventricular cavities (mean area of septum disorganized about 1 percent).

It should be emphasized that reference to disordered septal architecture in this review pertains specifically to malalignment between cardiac muscle cells. Light and electron microscopic studies of plastic-embedded ventricular septal myocardium from patients with hypertrophic cardiomyopathy have shown that both disorganized and normally arranged cells frequently show disarray of myofibrils and myofilaments.[26,27] However, disarray of these intracellular contractile elements has also been described in normally arranged muscle cells in human beings and animals with a variety of normal or diseased cardiac states,[26,98–102] and it appears to be a relatively nonspecific morphologic alteration.

Systolic Anterior Motion of the Anterior Mitral Leaflet

Correlation with ventricular outflow obstruction: In patients with hypertrophic cardiomyopathy, left ventricular outflow tract narrowing and obstruction are produced by apposition of the anterior mitral leaflet (often together with chordae tendineae) against the hypertrophied ventricular septum during mid systole.[13–16,103–110] This abnormal systolic anterior motion of the anterior mitral leaflet is a characteristic finding in patients with hypertrophic cardiomyopathy and outflow obstruction, and has been demonstrated with both angiography[103–106] and echocardiography.[13–16,107–109] Systolic anterior motion of the anterior mitral leaflet has also been used to estimate the severity of left ventricular outflow tract obstruction in hypertrophic cardiomyopathy.[16,107] In this regard, the magnitude and duration of such systolic anterior motion have been shown to correlate well with the magnitude of the intraventricular gradient measured at cardiac catheterization under basal conditions and with provocative maneuvers,[107] and have also been shown to be diminished or absent after operation (when the outflow gradient has been abolished).[111,112] This relation between systolic anterior motion of the anterior mitral leaflet and outflow obstruction has been disputed by others.[41,113,114] However, it has been our experience that when the anterior leaflet of the mitral valve makes prolonged contact with the septum, true anatomic obstruction is almost invariably present. Conversely, when systolic anterior motion of the anterior mitral leaflet is not present, obstruction is almost always absent.

Occurrence in other cardiac diseases and hemodynamic states: Just as asymmetric septal hypertrophy and septal disorganization cannot be considered pathognomonic hallmarks of hypertrophic cardiomyopathy, systolic anterior motion of the anterior mitral leaflet also has been shown with echocardiography to occur occasionally in a variety of other diseases and hemodynamic states (Fig. 1). The phenomenon of "pseudo SAM," which does not represent a true abnormality of mitral valve motion, has recently been reviewed[115] and will not be considered further here. Systolic anterior motion of the anterior mitral leaflet

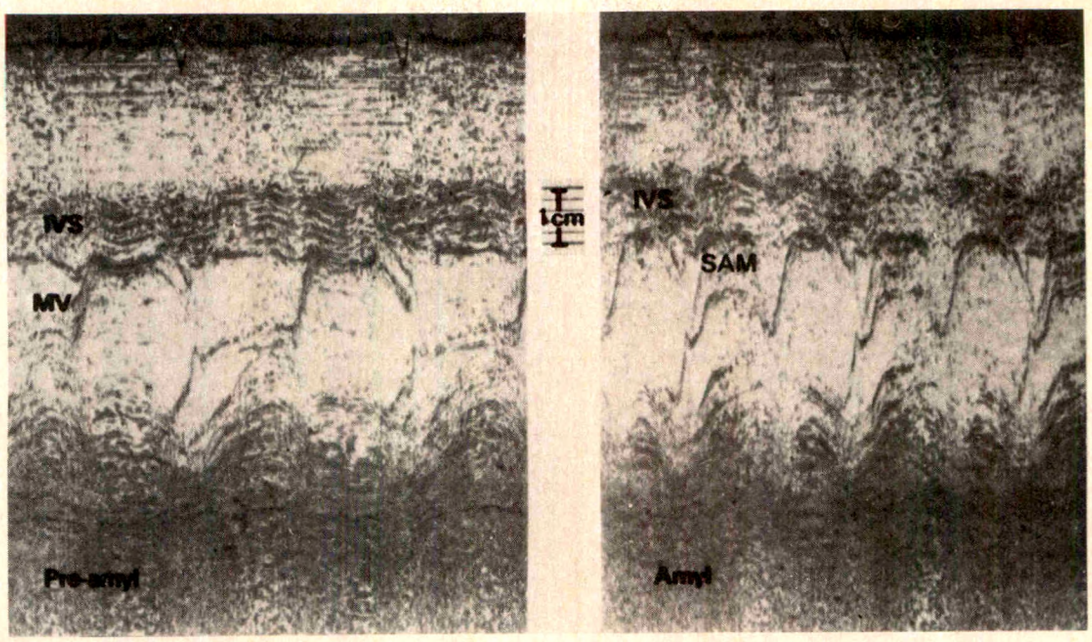

FIGURE 11. Echocardiogram recorded in a 47 year old man with concentric ventricular hypertrophy (and normal systemic blood pressure). Systolic anterior motion of the anterior mitral leaflet (SAM) is not present under basal conditions (Pre-amyl) but is present with the administration of amyl nitrite. IVS = ventricular septum; MV = mitral valve. Reproduced from Maron et al.[132] with permission of the American Heart Association, Inc.

has been identified in patients with complete (-d) transposition of the great vessels,[116–120] aortic valve stenosis,[41] aortic regurgitation,[121] hypovolemic shock,[122] discrete subaortic stenosis,[123] glycogen storage (Pompe's) disease of the heart,[124] Friedreich's ataxia with or without disproportionate septal thickening,[125] tunnel subaortic stenosis,[126] acquired valve disease associated with secondary disproportionate septal thickening,[127] coarctation of the aorta,[49] ischemic heart disease[110] and hypertensive heart disease.[128,129] Our review of published data disclosed primarily isolated reports of true systolic anterior motion of the anterior mitral leaflet in patients with cardiac diseases other than hypertrophic cardiomyopathy, and the majority of these reports describe relatively mild degrees of systolic anterior motion. The contention that true systolic anterior motion rarely occurs in the absence of hypertrophic cardiomyopathy is supported by echocardiographic data obtained (under basal conditions) in a large population of 721 infants, children and adults with a variety of cardiac and systemic diseases (unpublished data). True systolic anterior motion of the anterior mitral leaflet was present in only 3 percent of the overall study group, and hence the specificity of this finding for hypertrophic cardiomyopathy was extremely high (97 percent, Table II). However, the finding was particularly common (21 percent) in a subgroup of 51 patients with d-transposition of the great vessels.[116–119] When the study group, exclusive of those patients with transposition of the great vessels was analyzed, the prevalence of systolic anterior motion was only 1.6 percent. About 75 percent of these patients with systolic anterior motion (and diseases other than transposition of the great vessels) had disproportionate thickening of the ventricular septum. Hence, systolic anterior motion of the anterior mitral leaflet proved to be a particularly uncommon finding in a patient population with a normal septal/free wall thickness ratio (prevalence rate 0.4 percent; specificity 99 percent).

Nevertheless, systolic anterior motion of the anterior mitral leaflet is not a particularly sensitive marker for hypertrophic cardiomyopathy. This is necessarily true because, when marked, systolic anterior motion is almost invariably present only in patients with obstruction to left ventricular outflow; such patients represent a minority of all patients within the wide disease spectrum of hypertrophic cardiomyopathy.

Concentric (symmetric) hypertrophy: Systolic anterior motion of the anterior mitral leaflet (associated with hemodynamically documented left ventricular outflow obstruction) has also been described in patients without evidence of ventricular hypertrophy on echocardiographic study,[115,131] as well as in patients with concentric (symmetric) hypertrophy of the left ventricle.[113,132–134] Our experience[132] with the latter group indicates that most such patients demonstrate clinical, hemodynamic and angiographic features of typical hypertrophic cardiomyopathy. Some of these patients have evidence of genetic transmission of asymmetric septal hypertrophy and therefore their condition represents a variant of hypertrophic cardiomyopathy. Others, however, have no evidence of genetic transmission and must be regarded as having an idiopathic form of left ventricular hypertrophy. An example of systolic anterior motion of the anterior mitral leaflet in such a patient is illustrated in Figure 11. Hence, it appears that systolic anterior motion of the anterior mitral leaflet does occur, although rarely, in patients who have concentric hypertrophy not related to genetically transmitted hypertrophic cardiomyopathy.

Thirty patients with mitral regurgitation confirmed by left ventriculography were studied from a transcutaneous approach with combined use of the ultrasonic pulsed Doppler technique and cross-sectional echocardiography. The location of the abnormal Doppler signals was revealed with cross-sectional echocardiography, displayed in two dimensional images.

Abnormal Doppler signals, never detected in healthy subjects, were recorded during systole at the mitral area and in the left atrial cavity in patients with mitral regurgitation.

In the left atrial cavity, these signals were detected in 11 patients. They were either bidirectional or unidirectional and of a wide velocity range. The area in which these signals were detected was mapped on the cross-sectional echocardiogram, and the map was considered to show the main direction and distribution of regurgitant flow from the mitral ostium into the left atrial cavity. The main direction of the regurgitant flow determined with this method closely coincided with that revealed by angiocardiography.

At the mitral area, abnormal Doppler signals were detected in 28 patients. These signals were powerful, bidirectional and of a wide range of velocity. It is believed that these signals indicate not only the mitral regurgitant flow, but also the vibration of the mitral valve. Thus, the combined use of the ultrasonic pulsed Doppler technique and cross-sectional echocardiography is advantageous for the transcutaneous detection and analysis of regurgitant flow in mitral regurgitation.

The development of the ultrasonic pulsed Doppler technique[1,2] has permitted noninvasive analysis, from a transcutaneous approach, of the dynamics of intracardiac flow and its pathophysiologic meaning. In this study, we applied the ultrasonic pulsed Doppler technique in combination with M mode and cross-sectional echocardiography[3] to analyze the intracardiac flow pattern in mitral regurgitation.

Methods

Patients: The study group comprised 30 patients, aged 25 to 66 years, with mitral regurgitation and combined mitral stenosis and regurgitation. Patients with both mitral regurgitation and an aortic valve lesion were included. Mitral regurgitation was caused by rheumatic heart disease in 15 cases, ruptured chordae tendineae of the mitral valve in 5, prolapsed mitral leaflet in 3, subacute bacterial endocarditis in 2 and coronary heart disease in 2; the cause was unknown in 3 patients. In all 30 patients, mitral regurgitation was confirmed with cardiac catheterization and left ventriculography. Left ventriculography demonstrated the following grades of mitral regurgitation according to the classifi-

From the Division of Cardiology, Hospital and Research Institute,* National Cardiovascular Center, Osaka, Japan. This study was supported in part by the Scientific Research Grants for Health and Welfare Program of the Ministry of Health and Welfare of Japan in 1977, 1978 and 1979, and Grant-in Aid (487094) for Developmental Scientific Research from the Ministry of Education, Science and Culture of Japan in 1979. Manuscript received July 30, 1979; accepted September 6, 1979.

cation of Sellers et al.[4]: 1^+ in 3 patients, 2^+ in 6, 3^+ in 8 and 4^+ in 13. Ten healthy subjects were also studied for comparison.

Recording techniques: The equipment used consisted of a bidirectional ultrasonic pulsed Doppler flowmeter (Hitachi Medico EUD-4Z) in combination with a cross-sectional echocardiograph (Aloka SSD-120). The frequency of the pulsed Doppler flowmeter was 2.5 megahertz and the pulse repetition rate was 4.5 kilohertz. The Doppler signal was recorded simultaneously with the M mode echocardiogram, phonocardiogram and electrocardiogram using a strip chart recorder (Electronics for Medicine). The sampling site of the Doppler signal could be set at any depth from 0.5 to 15 cm from the transducer and was displayed on the simultaneously recorded M mode echocardiogram (Fig. 1). The width of sampling volume along the ultrasonic beam could be selected to be 2, 5 or 10 mm.

The search for the Doppler signals was performed by continuously moving the sampling site over a wide area around the mitral ostium and in the left atrial cavity with monitoring by the M mode echocardiogram. Then the cross-sectional echocardiogram was recorded along the long axis of the left ventricle at the phase of 100 ms after the R wave of the electrocardiogram, including the beam direction in which the abnormal Doppler signals were detected. After the direction of the Doppler beam and the sampling site were marked on the cross-sectional image, the Doppler signal at the site concerned was recorded with a real time, on-line sound spectrograph, showing flows toward and away from the transducer below and above the baseline, respectively (Fig. 1).

Results

Normal Doppler signals in left atrium and at mitral ostium: The following brief description of the Doppler signals obtained in the left atrial cavity and at the mitral ostium in the 10 healthy subjects provides a comparative basis for the findings in the patients with mitral regurgitation:

When the ultrasonic beam was superiorly transmitted from the third or fourth left sternal border into the left atrial cavity (Fig. 2, Beam 1) in the normal subjects, low frequency Doppler signals were recorded below the baseline in diastole, indicating slow flows toward the transducer, which were considered to be related to the diastolic inflow into the left ventricle. No significant Doppler signal was recorded in systole.

At the mitral ostium (Fig. 2, Beam 2) in these subjects, Doppler signals with two peaks were recorded below the baseline in diastole, indicating the mitral inflow from the atrium into the ventricle. In systole, only insignificant Doppler signals, believed to be caused by mitral valve motion, were recorded.

Doppler signals obtained in patients with mitral regurgitation (Fig. 3): *In the left atrial cavity,* pansystolic Doppler signals were recorded in some areas with the ultrasonic beam transmitted from the third or fourth left sternal border. These signals continued from the Doppler signal of mitral valve closure to that of

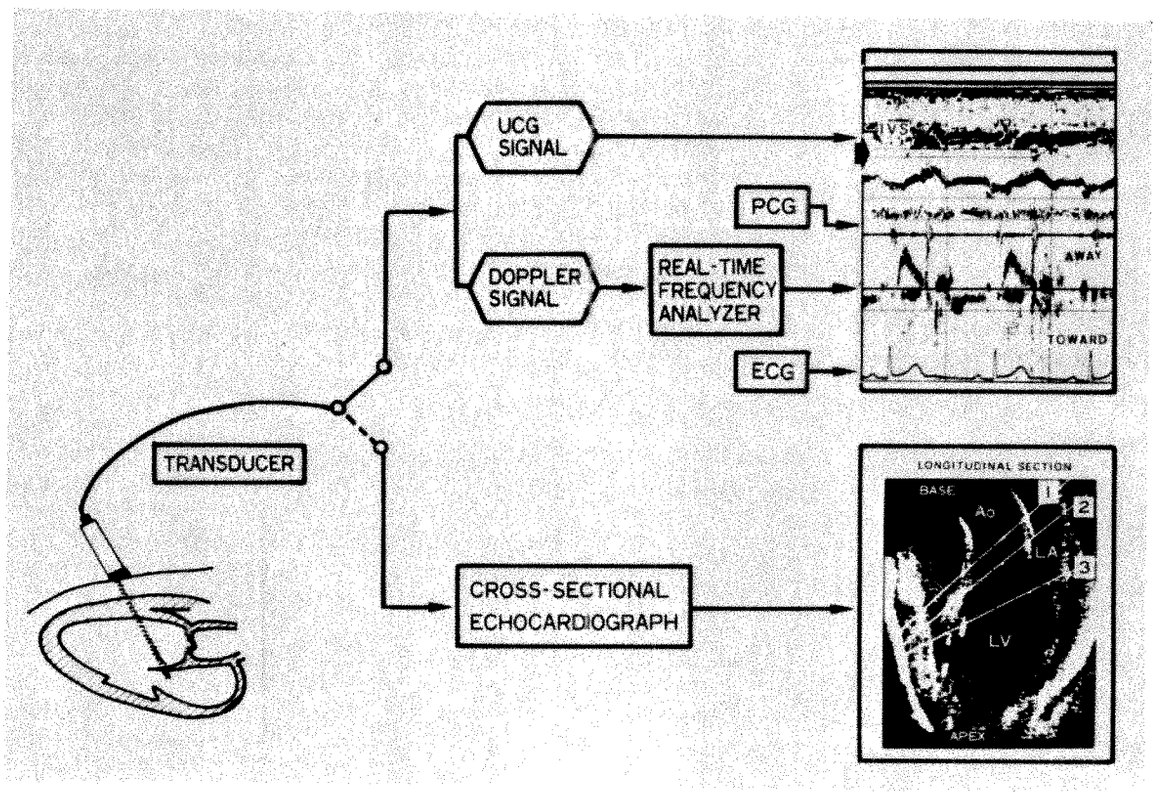

FIGURE 1. Schematic diagram of the system for detecting intracardiac blood flow. Ao = aorta; ECG = electrocardiogram; IVS = interventricular septum; LA = left atrium; LV = left ventricle; PCG = phonocardiogram; UCG = ultrasound cardiogram (M mode); 1, 2 and 3 = three ultrasonic beam directions in which Doppler signals are recorded; AWAY and TOWARD = direction of flow away and toward the transducer above and below the baseline, respectively.

mitral valve opening. They were either unidirectional or bidirectional and had a wide frequency range, indicating the coexistence of various velocity components such as those found in turbulent flow: The signals were detected in 11 of the 30 patients. All 11 patients manifested 2^+ or greater mitral regurgitation, but correlation between the incidence of these signals and the severity of mitral regurgitation was equivocal and requires future study.

The area in which these abnormal Doppler signals were detected was mapped on the cross-sectional echocardiogram in each case. This map was interpreted as revealing the main direction and distribution of regurgitant flow from the mitral ostium into the left atrial cavity.

At the mitral ostium (Fig. 4), powerful bidirectional Doppler signals with a wide frequency range were detected at the site where the echoes of the anterior and

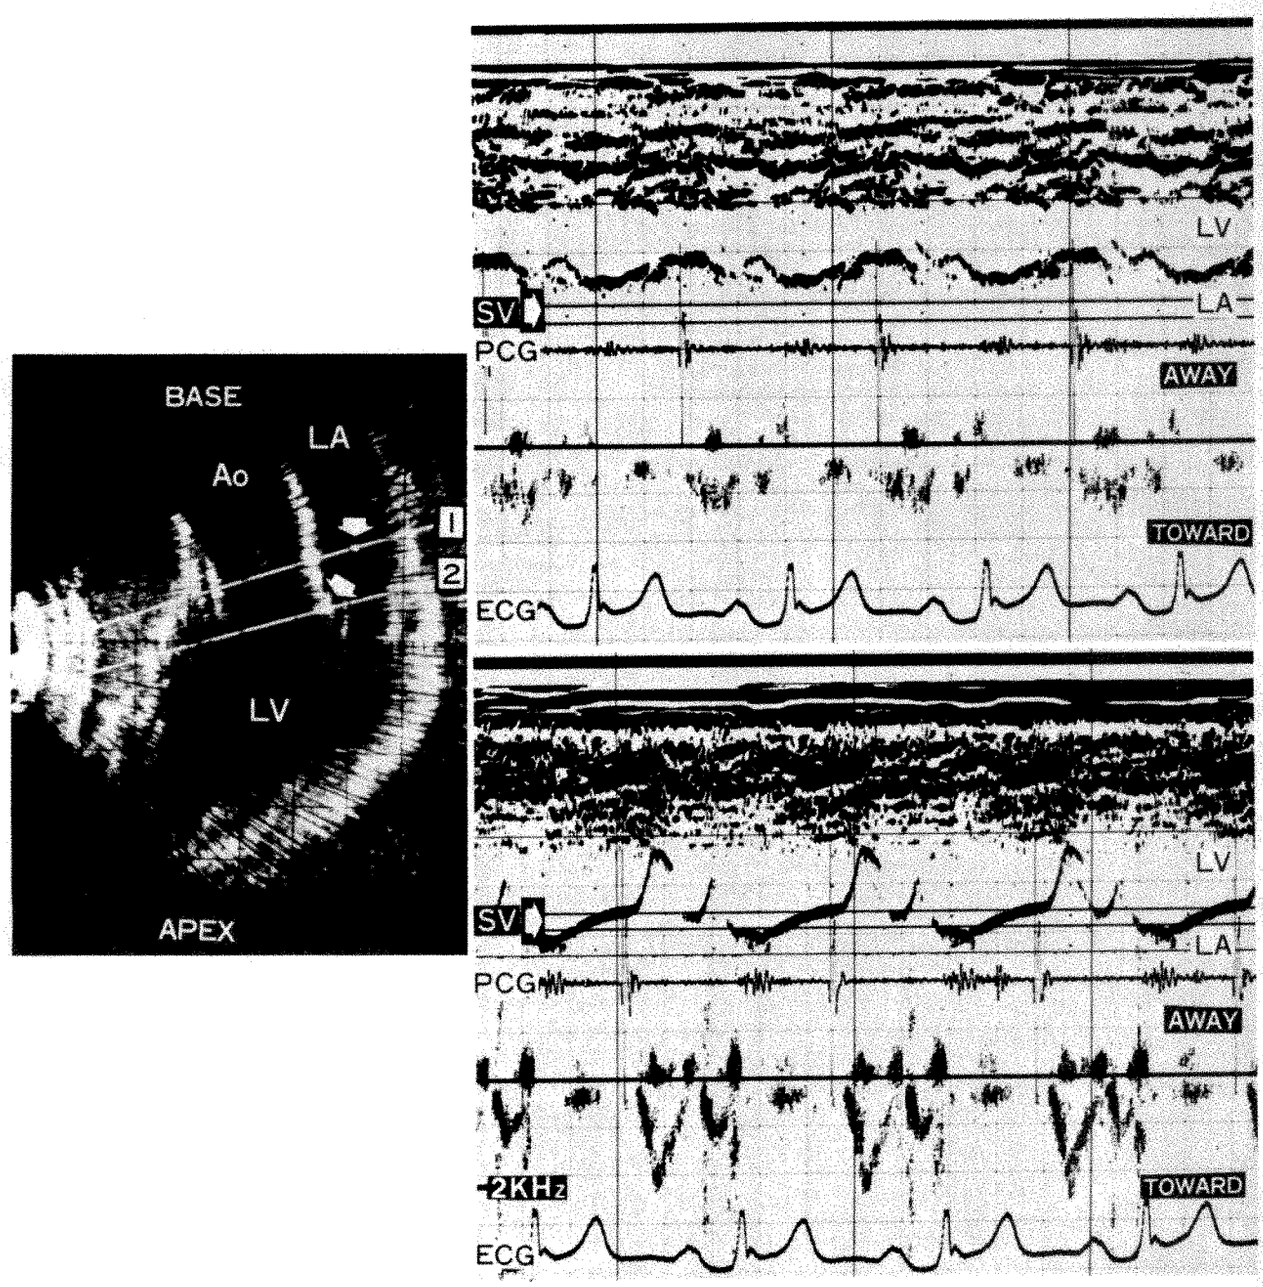

FIGURE 2. Intracardiac Doppler signals in a healthy subject. **Left,** cross-sectional echocardiogram along the long axis of the left ventricle, viewed from the left. The two **white lines** (Beams 1 and 2) represent the direction of the ultrasonic beams in the **upper right** and **lower right** panels, respectively. **Arrows** indicate the position of the sampling volume (SV) of the Doppler signals. Ao = aorta; LA = left atrium; LV = left ventricle. **Upper right,** the Doppler signals in the left atrial cavity obtained by Beam 1 are simultaneously recorded with the M mode echocardiogram in which the sampling site is displayed by a pair of lines (SV). Few signals are recorded in systole, although a slow flow is observed in diastole. **Lower right,** the recording at the mitral area obtained by Beam 2. Few signals are recorded in systole, although a diastolic inflow with two peaks is clearly recorded. ECG = electrocardiogram; PCG = phonocardiogram.

posterior mitral leaflets appeared to be coapted. These abnormal signals were observed in 28 of the 30 patients.

Representative Cases

Case 1 (Fig. 5): A 45 year old woman with rheumatic mitral valve disease. Left cineventriculography demonstrated 3+ mitral regurgitant flow toward the mid portion of the left atrial cavity. The intensity of the abnormal Doppler signals increased and then decreased as the sampling site was moved from the anterior to the posterior wall of the left atrium. The highest intensity was obtained in the mid portion of the left atrial cavity. This finding was interpreted as showing that the sampling site moved anteroposteriorly across the regurgitant flow that coursed from the mitral ostium to the mid portion of the atrial cavity. These alterations in the Doppler signal were observed in a wide area in the mid portion of the left atrial cavity. Mapping on the cross-sectional echocardiogram showed that the abnormal signals were distributed over the area extending from the mitral ostium to the mid portion of the left atrium. Thus, in this case, the mitral regurgitant flow was considered to be directed mainly from the mitral ostium to the mid portion of the atrial cavity.

Case 2 (Fig. 6): A 44 year old woman with ruptured chordae tendineae of the mitral valve. Left cineventriculography showed that the posterior mitral leaflet rolled up into the left atrium during systole. The contrast material regurgitated anterosuperiorly along the atrial side of the anterior mitral leaflet. The abnormal Doppler signals were localized in the anterior half of the left atrial cavity. These signals were bidirectional when recorded near the anterior wall of the left atrium and became unidirectional as the sampling site was moved into the mid portion of the left atrial cavity. This distribution of the abnormal Doppler signals corresponded approximately to the main direction of the regurgitant flow shown in the ventriculogram.

Discussion

The ultrasonic pulsed Doppler technique was developed by Baker[1] and Peronneau et al.[2] to examine the pattern of intracardiac flow. The M sequence modulated Doppler technique[5] was also designed for this purpose. Recent progress in development of the instrumentation has increased clinical application[6–13] of the technique in a variety of fields. In cases of mitral regurgitation, bidirectional Doppler signals with a wide range of frequency have been recorded at the mitral valve ostium. Because of the characteristic features of these abnormal Doppler signals, it is believed that they reflect the turbulent flow caused by regurgitation.[6,10]

In this study, we attempted to determine the main direction and distribution of the mitral regurgitant flow with reference to cardiac anatomy. The sampling site was located using both the ultrasonic pulsed Doppler technique and cross-sectional echocardiography[3] and displaying the sampling site on the cross-sectional image of the heart. With this combined procedure it was possible to demonstrate the distribution of the regurgitant flow in the left atrial cavity by moving the direction of the ultrasonic beam and the sampling site within the heart.

Doppler signals in the left atrial cavity: In patients with mitral regurgitation, the abnormal Doppler signals were detected in the left atrial cavity. The time of occurrence and the location of such signals were consistent with the characteristics of mitral regurgitant flow. Furthermore, because these abnormal Doppler signals have never been seen in healthy subjects they were considered to be related to mitral regurgitant flow. Using M mode echocardiography as a monitor, Johnson

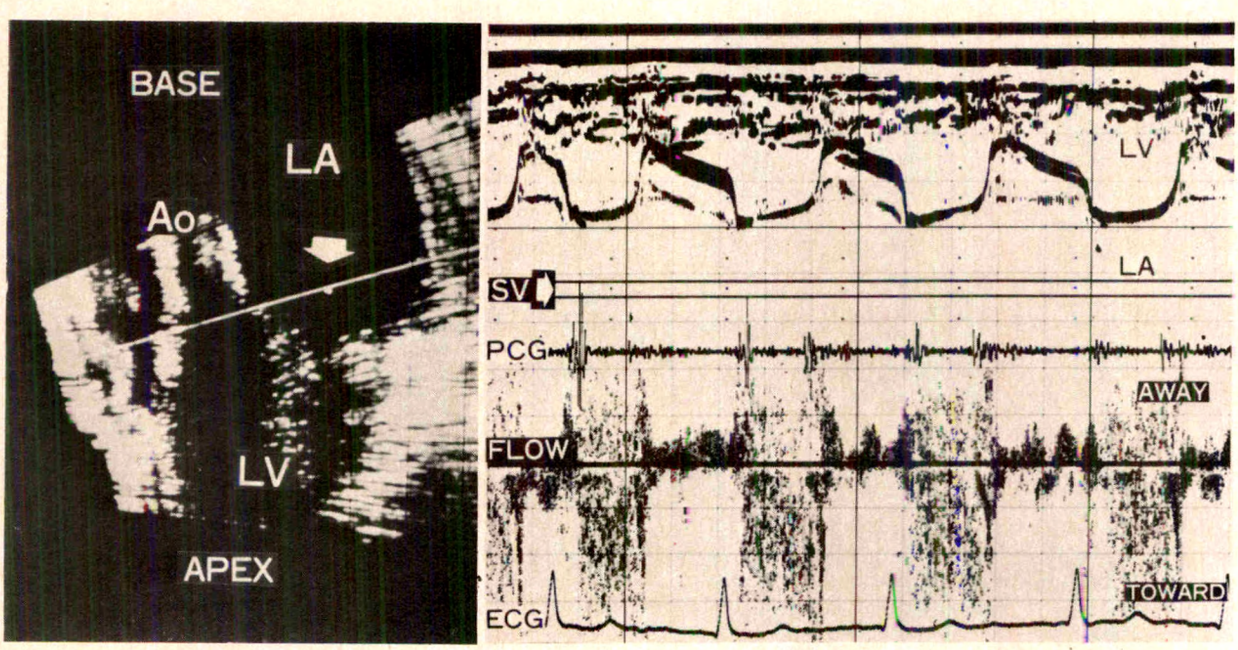

FIGURE 3. Abnormal Doppler signals in the left atrial cavity in a patient with rheumatic mitral regurgitation. **Left,** the **white line** shows the beam direction and the position of the sampling volume (SV). **Right,** abnormal Doppler signals detected at the sampling site. They are harsh and have a bidirectional wide range of velocity. Abbreviations as in Figure 2.

and co-workers[6,10] found bidirectional Doppler signals in the left atrium of patients with mitral regurgitation and believed that these signals reflected the turbulent jet of regurgitation. In our study, the site of the distribution of abnormal Doppler signals was confirmed with the use of cross-sectional echocardiography. We found both bidirectional and unidirectional abnormal Doppler signals in the left atrial cavity of our patients. The bidirectional Doppler signals may have been due to turbulence of the mitral regurgitant flow, which may have acted like a vortex. It is also possible that unidirectional flow was falsely recorded as bidirectional flow, because the ultrasonic beam struck the blood flow perpendicularly. However, we ruled out the latter possibility for two reasons: (1) The bidirectional signals were obtained using ultrasonic beams that were aimed in various directions, and (2) the intensity of bidirectional signals caused by such a mechanism would usually be weak, whereas these signals were strong. Thus, we considered turbulent flow to be the cause of the bidirectional signals in our study.

The unidirectional signals were believed to be recorded when the sampling site touched the main stream of regurgitant flow. However, there is a small possibility that the weaker of the two components of the bidirectional flow was not sufficiently displayed because of inadequacy of our recording system. This possibility requires further study.

The abnormal Doppler signals were recorded as bidirectional in the left atrial cavity in 8 of the 11 patients.

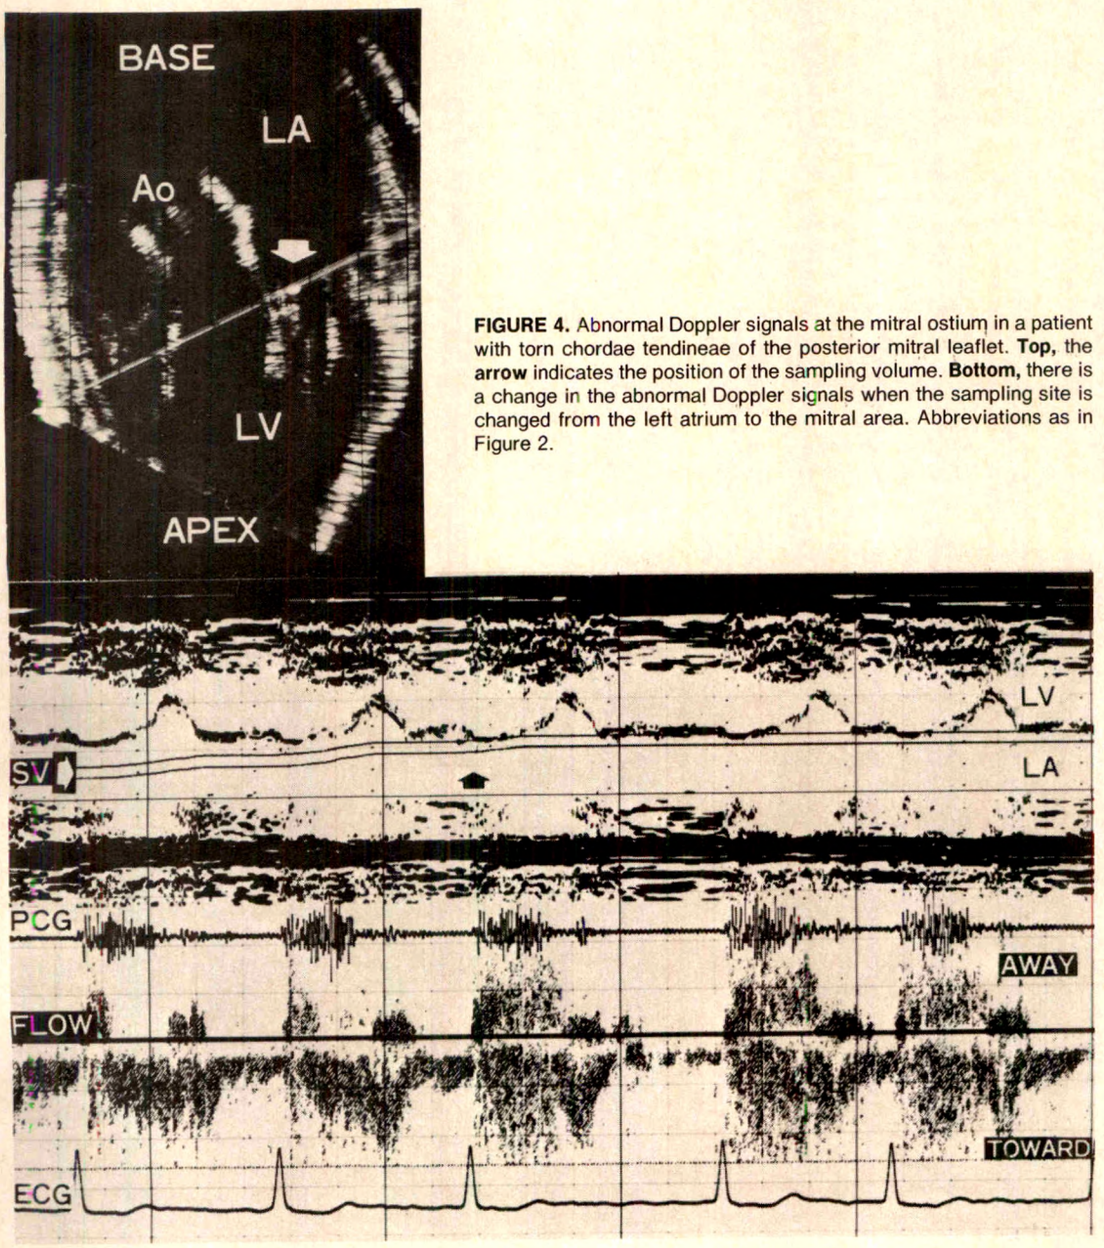

FIGURE 4. Abnormal Doppler signals at the mitral ostium in a patient with torn chordae tendineae of the posterior mitral leaflet. **Top,** the **arrow** indicates the position of the sampling volume. **Bottom,** there is a change in the abnormal Doppler signals when the sampling site is changed from the left atrium to the mitral area. Abbreviations as in Figure 2.

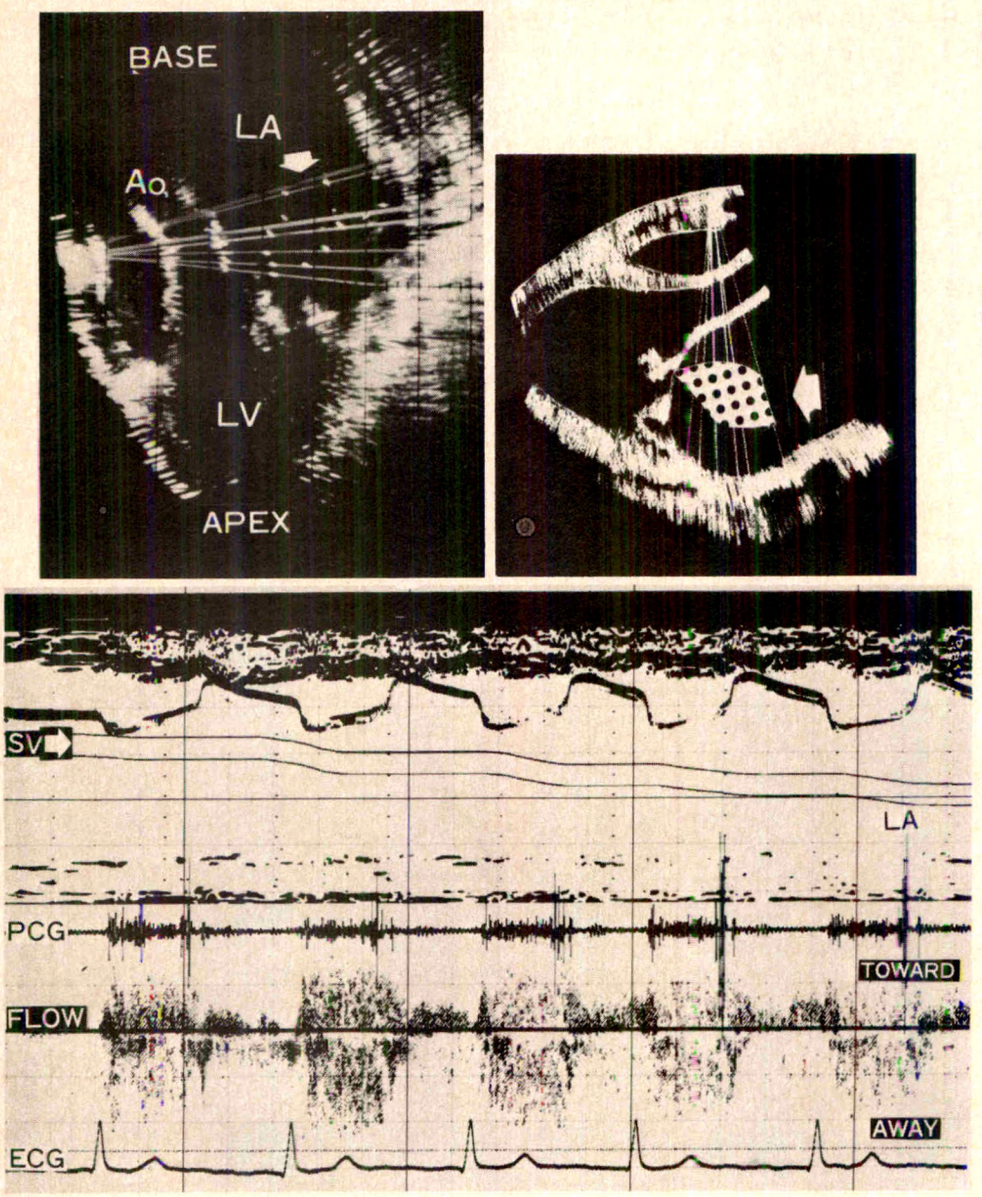

FIGURE 5. Abnormal Doppler signal in the middle area of the left atrial cavity in a patient with rheumatic mitral regurgitation. **Upper left,** the **white lines** indicate the directions of the ultrasonic beam. The abnormal Doppler signals were recorded in the ranges between the **two white points** on each line. An area encircled by these **white points** is interpreted to be the extent of regurgitant flow. **Upper right,** schematic illustration of the extent of regurgitant flow in the left atrial cavity. **Bottom,** the abnormal Doppler signals recorded when there was a change in the depth of the sampling volume along the beam direction (**arrow** in the **upper left panel**). Abbreviations as in Figure 2.

We considered the mitral regurgitant flow in the left atrial cavity of our patients to be mainly turbulent. Johnson[10] also reported that the abnormal Doppler signals were bidirectional in the left atrial cavity, although the location of the sampling site in their study was confirmed not with cross-sectional but with M mode echocardiography. Kalmanson et al.[11] recorded unidirectional mitral regurgitant flow, using a zero-crossing counter. However, this counter displays the sum of the components of the signal. In addition, in their study, the ultrasonic beam was transmitted from the apical region. With such a beam direction, regurgitant flow might be represented as unidirectional because the main stream of the regurgitant flow would be detected as the total flow.

In one of our patients with ruptured chordae tendineae of the mitral valve (Case 2), the regurgitant flow was judged to be directed along the anterior margin of the left atrium. In this patient, the abnormal Doppler signal was unidirectional in the mid portion of the left atrial cavity but bidirectional near the anterior wall of the left atrium. Thus, it is highly probable that the bidirectional abnormal Doppler signals were due to turbulence produced by regurgitant blood flow striking the anterior wall of the left atrium. However, they may also have been caused in part by vibration of the left anterior atrial wall induced by the regurgitant flow.

Mapping of the abnormal Doppler signals on the cross-sectional echocardiogram revealed that the distribution of regurgitant flow in the left atrium differed among patients. For example, this flow was found in the anterior part of the left atrium in some patients and in the mid part in other patients. Such an area of distribution extending from the mitral ostium into the left

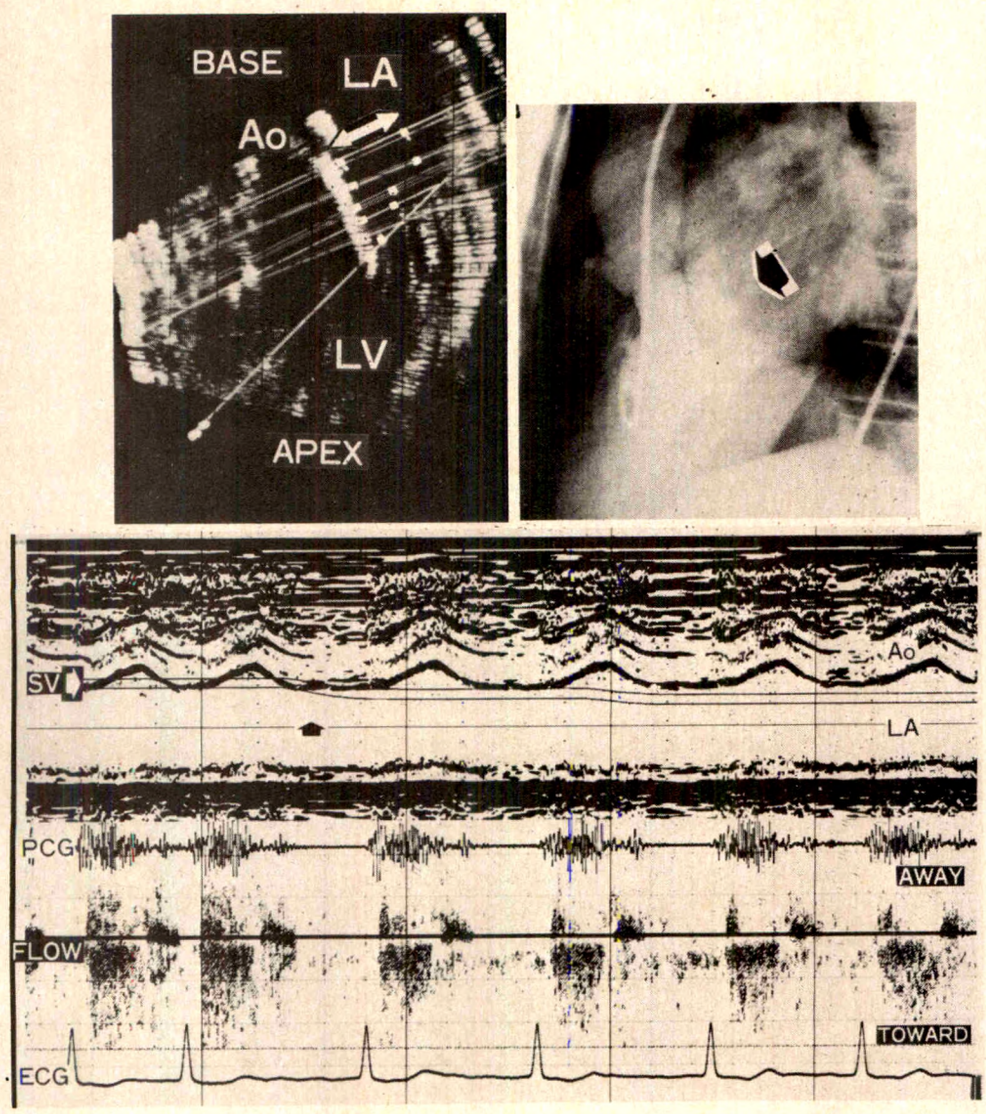

FIGURE 6. Abnormal Doppler signals in a patient with torn chordae tendineae of the posterior mitral leaflet. **Upper left, white lines** indicate the directions of the ultrasonic beam. The abnormal Doppler signals were recorded in the ranges between the **two white points** on each line. The area in which the abnormal Doppler signals were detected was localized in the anterior half of the left atrial cavity. **Upper right,** the lateral view of the angiocardiogram of the left ventricle and the left atrium. The **black arrow** indicates the regurgitant flow. **Bottom,** the abnormal Doppler signals recorded when there was a change in the depth of the sampling volume (**arrow** in **upper left panel**). Abbreviations as in Figure 2.

atrial cavity was considered to represent the main stream of mitral regurgitant flow. This main stream was consistent with that detected on angiocardiography.

The abnormal Doppler signals in the left atrial cavity were found in only 11 of the 30 patients. There are two possible reasons for this low detection rate: (1) It is difficult to capture the regurgitant flow when the ultrasonic beam is far from the chest wall, and (2) the sensitivity of the equipment used was insufficient to detect the Doppler signal from the deep-lying left atrial cavity in all patients examined. The rate of detecting regurgitant flow should improve as examiners gain increased technical skill and the sensitivity of the equipment is refined.

Doppler signals at the mitral ostium area: Powerful Doppler signals were detected at the area of the mitral ostium in 28 of the 30 patients examined. These signals were invariably bidirectional. Their bidirectional quality and wide frequency range were similar to those of Doppler signals due to the mitral valve vibration caused by aortic regurgitation.[14,15] Systolic mitral vibration has also been reported by others[16] in M mode echocardiographic studies in patients with mitral regurgitation. Thus, the bidirectional Doppler signals at the mitral valve area may result not only from the regurgitant flow, but also from the vibration of the mitral valve surrounding the ostium. Further study is required to elucidate these points.

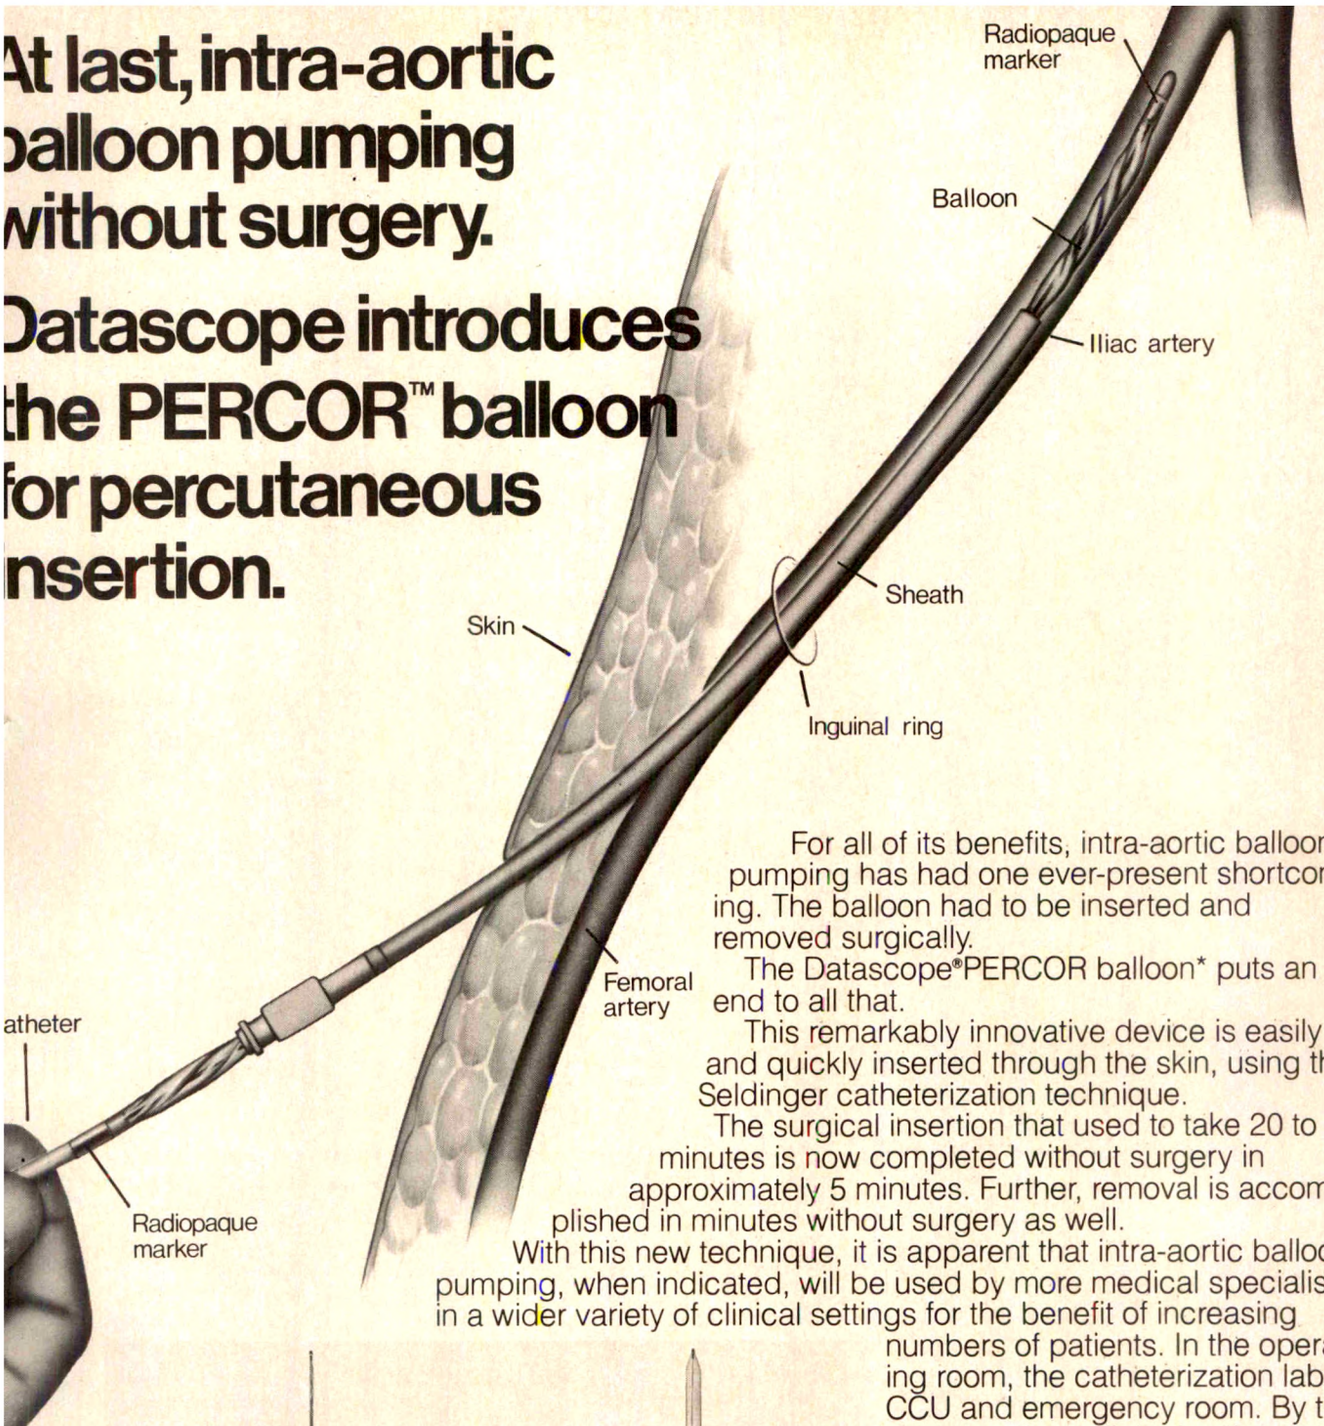
At last, intra-aortic balloon pumping without surgery.

Datascope introduces the PERCOR™ balloon for percutaneous insertion.



For all of its benefits, intra-aortic balloon pumping has had one ever-present shortcoming. The balloon had to be inserted and removed surgically.

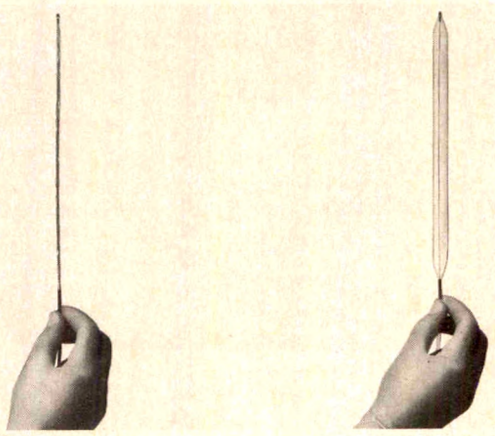
The Datascope®PERCOR balloon* puts an end to all that.

This remarkably innovative device is easily and quickly inserted through the skin, using the Seldinger catheterization technique.

The surgical insertion that used to take 20 to 45 minutes is now completed without surgery in approximately 5 minutes. Further, removal is accomplished in minutes without surgery as well.

With this new technique, it is apparent that intra-aortic balloon pumping, when indicated, will be used by more medical specialists in a wider variety of clinical settings for the benefit of increasing numbers of patients. In the operating room, the catheterization lab, CCU and emergency room. By the surgeon, the radiologist, the cardiologist.

We would be pleased to send you more information about our revolutionary device and to schedule a filmed demonstration of its use. Call Robert Rewolinski, Manager, Cardiac Assist Products, at 201-265-8800 or write him at Datascope Corp., Dept. #5-S, 580 Winters Avenue, Paramus, NJ 07652.



PERCOR™ balloon ready for insertion.

PERCOR™ inflated.

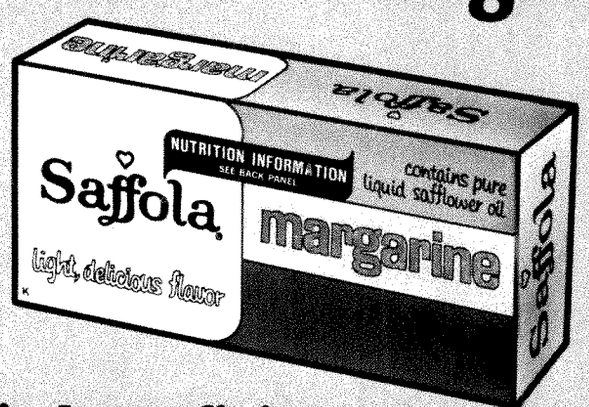
Saffola® fights cholesterol better than any corn oil margarine.



Higher in beneficial polyunsaturates. Contains no cholesterol. And tastes great.

Saffola is beneficial as part of a fat modified diet to help reduce serum cholesterol.

THE ROGERS HEART FOUNDATION

. . . . . is pleased to announce our 1980 Continuing Education Meetings. To keep abreast of current cardiology, join us this year o relaxing beaches of Florida; travel with us to the colorful Hispanic charm of Old Mexico, to the nostalgic Klondike Days in Cana to the world's oldest kingdom to enjoy the Tivolian magic of Copenhagen. We proudly continue to offer you seminars of the hi caliber in unequalled surroundings.

If you would like to be on the Rogers Heart Foundation's mailing list for all Continuing Education Meetings, fill out the form b and mail to Rogers Heart Foundation, St. Anthony's Hospital, 601 12th St. North, St. Petersburg, Florida 33705, (813–894-0 Individual programs will be printed and available three to four months prior to date of each meeting.

March 29 - April 3, 1980

13th Annual Physicians Workshop in Electrocardiography
Maria Isabella Sheraton Hotel
Mexico City, Mexico
Fee: $150 (U.S.)
Credit Hours: 30
Directors: Henry J. L. Marriott, M.D.
Demetrio Sodi-Pallares, M.D.

May 3-6, 1980

5th Annual Symposium on Cardiovascular Nursing
Carillon Hotel
Miami Beach, Florida
Fee: $150 (U.S.)
Directors: Henry J. L. Marriott, M.D.
Leo Schamroth, M.D.
Faculty: International

July 19-22, 1980

5th Canadian Summer Workshop in Electrocardiography
Hotel MacDonald
Edmonton, Alberta
Fee: $125 (U.S.)
Credit Hours: 24
Director: Henry J. L. Marriott, M.D.

August 30 - Sept. 6, 1980

18th Annual Seminar in Cardiology
Hotel Scandinavia
Copenhagen, Denmark
Fee: $250 (U.S.)
Credit Hours: 24
Director: Henry J. L. Marriott, M.D
Faculty: International

Oct. 30 - Nov. 3, 1980

21st Workshop in Electrocardiography Nurses & Physicians
Sheraton Sand Key Hotel
Clearwater Beach, Florida
Fee: $125 (U.S.)
Credit Hours: 25
Director: Henry J. L. Marriott, M.D

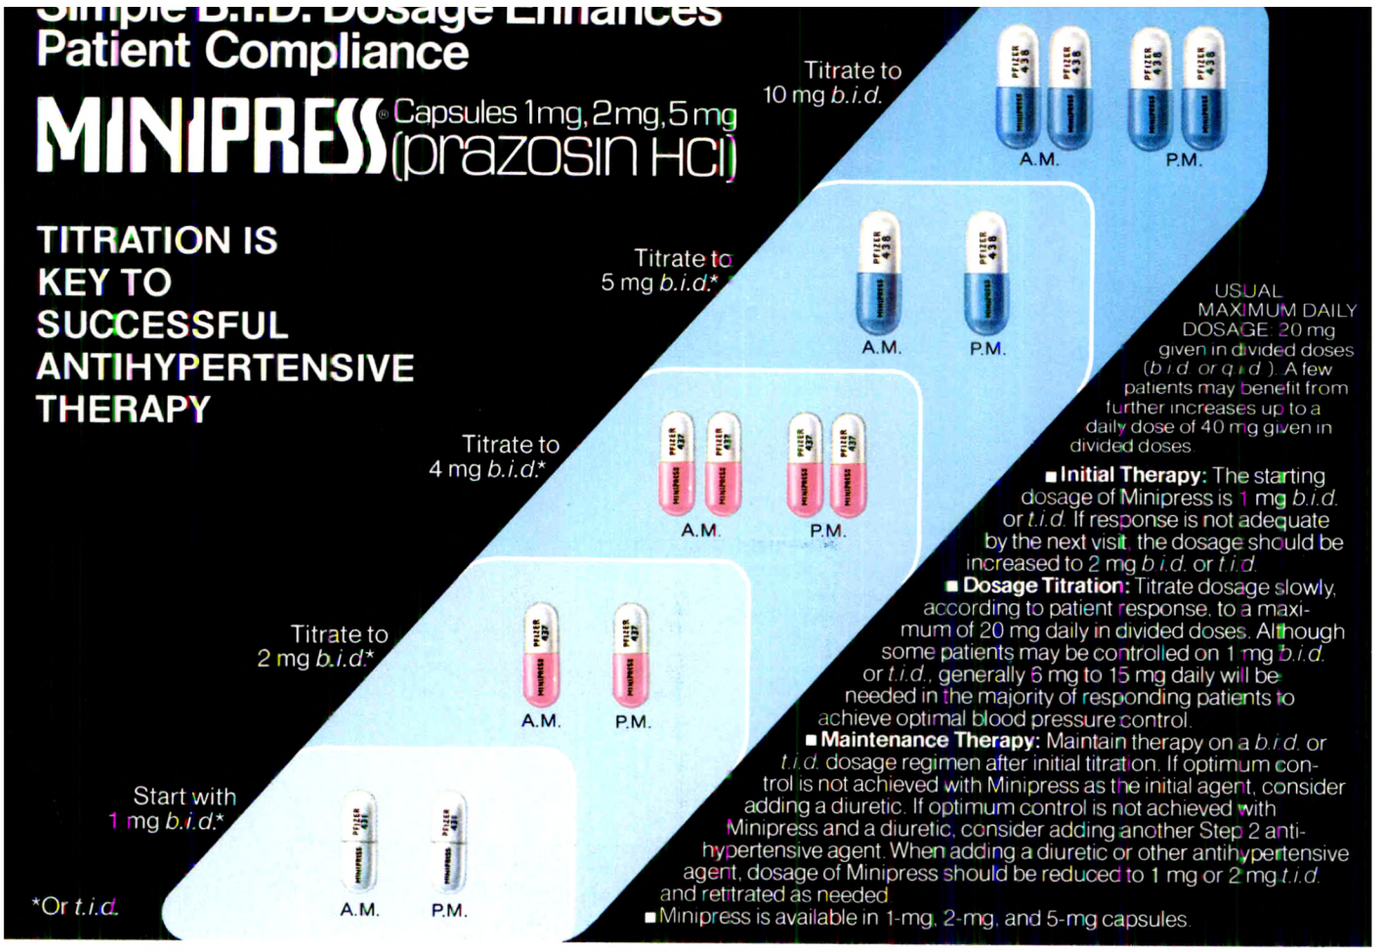
Please see Brief Summary on last page.
Before prescribing Minipress, WARNINGS and DOSAGE AND ADMINISTRATION

MINIPRESS® Capsules 1mg, 2mg, 5mg
(prazosin HCl)



BRIEF SUMMARY

MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*

INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established).

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus.

Genitourinary: urinary frequency, incontinence, impotence.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings).

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy, however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

WHEN YOU SUSPECT OR DETEC VENOUS THROMBOSIS...

Thromboembolism: a high risk among patients with one or more of these factors...

Advanced age
Fractures of lower limb
Hip surgery
Pelvic or abdominal surgery with extensive dissection
Previous venous thromboembolism
Congestive cardiac failure
Cancer surgery
Obesity
Varicose vein surgery

Incidence of venous thrombosis or abnormal scans as shown by ^{125}I-fibrinogen screening in selected high-risk medical-surgical patients

Category	Incidence
Elective surgery	
Major abdominal thoracic/gynecologic	11-65%[1,2]
Retropubic prostatectomy	28-50%[1,2]
Transurethral prostatectomy	4%[1,2]
Emergency surgery	
Hip fracture	48-74%[1,2]
Childbirth	3%[1,2]
Medical	
Myocardial infarction	23-38%[1,2]
Stroke	60%[1]

ORAL ANTICOAGULATION:
Often indicated to lower the risk of thromboembolic complications.

References: 1. Hirsh J, Gallus AS: ^{125}I-labeled fibrinogen scanning. Use in the diagnosis of venous thrombosis. *JAMA 233*:970-973, 1975. **2.** Kakkar VV: The diagnosis of deep vein thrombosis using the ^{125}I-fibrinogen test. *Arch Surg 104*:152-159, 1972. **3.** Ebert RV: Use of anticoagulants in acute myocardial infarction. *Circulation 45*:903-910, Apr 1972. **4.** Borden CW: The current status of therapy with anticoagulants. *Med Clin North Am 56*:235-251, Jan 1972. **5.** Hirsh J, Gallus AS: Anticoagulants in venous thromboembolism. *For selected patients who have had a large infarct, a history of previous infarction or angina, severe hypotension or shock, chronic atrial fibrillation, congestive heart failure, past history of venous thrombosis or embolism or complications requiring a prolonged period in bed.

Endo Laboratories DUPONT

COUMADIN is an Endo registered U.S. trademark.

The oral anticoagulant of choice:

Tablets
COUMADIN®
crystalline warfarin sodium

singled out by more than 20 years of experience

Effective prophylaxis and treatment of venous thrombosis
Effective prophylaxis and treatment of pulmonary embolism
Effective treatment of atrial fibrillation with embolization
Effective adjunctive treatment of coronary occlusion

Initiation of therapy

Induction—40 to 60 mg for average adult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Alternatively, the large priming dose may be decreased for all patients to minimize the possibility of excessive increases in prothrombin time. Induction may be initiated with 10 to 15 mg daily and thereafter (usually 2 or 3 days) adjusted according to prothrombin time response.

- dosage must be individualized according to patient's prothrombin time
- frequent laboratory monitoring is recommended
- determine prothrombin time daily until results fall within the therapeutic range—1.5 to 2.5 times normal
- afterwards, prothrombin time must be determined periodically to monitor the patient's course

Maintenance of anticoagulation

- 2-10 mg, for most patients (scored tablets allow flexibility and accurate titration)
- dose and interval should be adjusted according to the individual patient's prothrombin time response

Duration of anticoagulation

- should be individualized for each patient
- in general, should be continued until danger of thrombosis and embolism has passed

Recommendations of prominent clinicians on duration of therapy

in myocardial infarction[3,4*]	1-3 years* (reevaluate at least every 6 months)
in pulmonary embolism[4,5]	6 weeks-6 months
in deep vein thrombosis[4,5]	6 weeks-6 months

Before prescribing, please see full product information on next page.

COUMADIN®

Tablets

for long- and short-term oral anticoagulation...

crystalline warfarin sodium, U.S.P.*

DESCRIPTION COUMADIN (crystalline warfarin sodium), a prothrombinopenic anticoagulant, is chemically crystalline sodium warfarin isopropanol clathrate. The crystallization of warfarin sodium virtually eliminates trace impurities present in amorphous warfarin sodium, thus achieving a crystalline product of the highest purity. Warfarin* is the coined generic name for 3-(α-Acetonylbenzyl)-4-hydroxycoumarin. On a dose-for-dose basis, COUMADIN (crystalline warfarin sodium) is therapeutically equivalent to amorphous warfarin sodium.

ACTIONS COUMADIN and other coumarin anticoagulants act by depressing synthesis in the liver of several factors which are known to be active in the coagulation mechanisms in a variety of diseases characterized by thromboembolic phenomena. The resultant **in vivo** effect is a sequential depression of Factors VII, IX, X and II. The degree of depression is dependent upon the dosage administered. Anticoagulants have no direct effect on an established thrombus, nor do they reverse ischemic tissue damage. However, once a thrombosis has occurred, anticoagulant treatment aims to prevent further extension of the formed clot and prevents secondary thromboembolic complications which may result in serious and possible fatal sequelae.

After oral administration, absorption is essentially complete, and maximal plasma concentrations are reached in 1 to 9 hours. Approximately 97% is bound to albumin within the plasma. COUMADIN usually induces hypoprothrombinemia in 36 to 72 hours, and its duration of action may persist for 4 to 5 days, thus producing a smooth, long lasting response curve. Little is known of the metabolic pathways involved in the biotransformation of oral anticoagulants in man. However, their metabolites appear to be eliminated principally in the urine.

INDICATIONS Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: COUMADIN is indicated for the prophylaxis and treatment of venous thrombosis and its extension, the treatment of atrial fibrillation with embolization, the prophylaxis and treatment of pulmonary embolism, and as an adjunct in the treatment of coronary occlusion.

"Possibly" effective: as an adjunct in the treatment of transient cerebral ischemic attacks.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATIONS Anticoagulation is contraindicated in any localized or general physical condition or personal circumstance in which the hazard of hemorrhage might be greater than its potential clinical benefits, such as:

Pregnancy—COUMADIN is contraindicated in pregnancy because the drug passes through the placental barrier and may cause fatal hemorrhage to the fetus in utero. Furthermore, there have been reports of birth malformations in children born to mothers who have been treated with warfarin during pregnancy. Women of childbearing potential who are candidates for anticoagulant therapy should be carefully evaluated and the indications critically reviewed with the patient. If the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the possibility of termination of the pregnancy should be discussed in light of those risks.

Hemorrhagic tendencies or blood dyscrasias. Recent or contemplated surgery of: (1)central nervous system; (2)eye; (3)traumatic surgery resulting in large open surfaces. **Bleeding tendencies associated with active ulceration or overt bleeding of:** (1)gastrointestinal, genitourinary or respiratory tracts; (2)cerebrovascular hemorrhage; (3)aneurysms—cerebral, dissecting aorta; (4)pericarditis and pericardial effusions; (5)subacute bacterial endocarditis. **Threatened abortion,** eclampsia and preeclampsia. **Inadequate laboratory facilities** or unsupervised senility, alcoholism, psychosis, or lack of patient cooperation. **Spinal puncture** and other diagnostic or therapeutic procedures with potential for uncontrollable bleeding. **Miscellaneous:** major regional, lumbar block anesthesia and malignant hypertension.

WARNINGS Warfarin sodium is a potent drug with a half-life of 2½ days; therefore its effects may become more pronounced as daily maintenance doses overlap. It cannot be emphasized too strongly that treatment of each patient is a highly individualized matter. Dosage should be controlled by periodic determinations of prothrombin time or other suitable coagulation tests. Determinations of whole blood clotting and bleeding times are not effective measures for control of therapy. Heparin prolongs the one-stage prothrombin time. Therefore, to obtain a valid prothrombin time when heparin and COUMADIN are given together, a period of at least 5 hours should elapse after the last intravenous dose and 24 hours after the last subcutaneous dose of heparin, before blood is drawn.

Caution should be observed when warfarin sodium is administered in any situation or physical condition where added risk of hemorrhage is present.

Administration of anticoagulants in the following conditions will be based upon clinical judgment in which the risks of anticoagulant therapy are weighed against the risk of thrombosis or embolization in untreated cases. The following may be associated with these increased risks:

Lactation—coumarins may pass into the milk of mothers and cause a prothrombinopenic state in the nursing infant. **Severe to moderate hepatic or renal insufficiency. Infectious diseases or disturbances of intestinal flora**—sprue, antibiotic therapy. **Trauma** which may result in internal bleeding. **Surgery or trauma** resulting in large exposed raw surfaces. **Indwelling catheters. Severe to moderate hypertension. Miscellaneous:** polycythemia vera, vasculitis, severe diabetes, severe allergic and anaphylactic disorders.

Patients with congestive heart failure may become more sensitive to COUMADIN, thereby requiring more frequent laboratory monitoring, and reduced doses of COUMADIN.

Concurrent use of anticoagulants with streptokinase or urokinase is not recommended and may be hazardous. (Please note recommendations accompanying these preparations.)

Abrupt cessation of anticoagulant therapy is not generally recommended; taper dose gradually over three to four weeks.

PRECAUTIONS Periodic determination of prothrombin time or other suitable coagulation test is essential.

Numerous factors, alone or in combination, including travel, changes in diet, environment, physical state and medication may influence response of the patient to anticoagulants. It is generally good practice to monitor the patient's response with additional prothrombin time determinations in the period immediately after discharge from the hospital, and whenever other medications are initiated, discontinued or taken haphazardly. The following factors are listed for your reference; however, other factors may also affect the prothrombin response.

The following factors, alone or in combination, may be responsible for increased prothrombin time response:

ENDOGENOUS FACTORS: Carcinoma; collagen disease; congestive heart failure; diarrhea; elevated temperature; hepatic disorders—infectious hepatitis, jaundice; poor nutritional state; vitamin K deficiency—steatorrhea.

EXOGENOUS FACTORS: Alcohol†; allopurinol; aminosalicylic acid; anabolic steroids; antibiotics; bromelains; chloral hydrate†; chlorpropamide; chymotrypsin; cimetidine; cinchophen; clofibrate; COUMADIN (crystalline warfarin sodium) overdosage; dextran; dextrothyroxine; diazoxide; dietary deficiencies; diuretics†; disulfiram; drugs affecting blood elements; ethacrynic acid; glucagon; hepatotoxic drugs; indomethacin; inhalation anesthetics; mefenamic acid; methyldopa; methylphenidate; metronidazole; monoamine oxidase inhibitors; nalidixic acid; oxolinic acid; oxyphenbutazone; phenylbutazone; phenyramidol; prolonged hot weather; prolonged narcotics; quinidine; quinine; salicylates; sulfinpyrazone; sulfonamides, long acting; thyroid drugs; tolbutamide; triclofos sodium; trimethoprim/sulfamethoxazole; unreliable prothrombin time determinations.

The following factors, alone or in combination, may be responsible for decreased prothrombin time response:

ENDOGENOUS FACTORS: Diabetes mellitus; edema; hereditary resistance to coumarin therapy; hyperlipemia; hypothyroidism.

EXOGENOUS FACTORS: Adrenocortical steroids; alcohol†; antacids; antihistamines; barbiturates; chloral hydrate†; chlordiazepoxide; cholestyramine; COUMADIN underdosage; diet high in vitamin K (vegetables, fish, fish oil, onions); diuretics†; ethchlorvynol; glutethimide; griseofulvin; haloperidol; meprobamate; oral contraceptives; paraldehyde; primidone; rifampin; unreliable prothrombin time determinations; vitamin C.

†Increased and decreased prothrombin time responses have been reported.

*Present as crystalline sodium warfarin isopropanol clathrate.

A patient may be exposed to a combination of the above factors, some of which may increase and some decrease his sensitivity to COUMADIN. Because the net effect on his prothrombin time response may be unpredictable under these circumstances, more frequent laboratory monitoring is advisable.

Drugs not yet shown to interact or not to interact with coumarins are best regarded with suspicion, and when their administration is started or stopped, the prothrombin time should be determined more often than usual.

Coumarins also affect the action of other drugs. Hypoglycemic agents (chlorpropamide and tolbutamide) and anticonvulsants (diphenylhydantoin and phenobarbital) may accumulate in the body as a result of interference with either their metabolism or excretion.

ADVERSE REACTIONS Potential side effects of COUMADIN (crystalline warfarin sodium) include:

1. Minor or major hemorrhage from any tissue or organ—which is an extension of the physiologic activity of prothrombinopenia. The signs and symptoms will vary according to the location and degree or extent of the bleeding. Therefore the possibility of hemorrhage should be considered in evaluating the condition of any anticoagulated patient with complaints which do not indicate an obvious diagnosis. Bleeding during anticoagulant therapy does not always correlate with prothrombin activity. (See TREATMENT FOR OVERDOSAGE.)

Bleeding which occurs when the prothrombin time is within the therapeutic range warrants diagnostic investigation since it may unmask a previously unsuspected lesion, e.g. tumor, ulcer, etc.

2. Side effects other than hemorrhage are infrequent and consist of alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramping, a syndrome called "purple toes," hypersensitivity reactions and a reaction consisting of hemorrhagic infarction and necrosis of the skin.

3. Priapism has been associated with anticoagulant administration, however, a causal relationship has not been established.

DOSAGE AND LABORATORY CONTROL The aim of anticoagulant therapy is to impede the coagulation or clotting mechanism to such an extent that thrombosis will not occur, but at the same time avoiding such extensive impairment as might produce spontaneous bleeding. Effective therapeutic levels with minimal complications can best be achieved in cooperative and well-instructed patients, who keep the doctor informed of their status between visits. COUMADIN patient aids are available to physicians on request.

The administration and dosage of COUMADIN must be individualized for each patient according to the particular patient's sensitivity to the drug as indicated by the prothrombin time. The prothrombin time reflects the depression of vitamin K dependent Factors VII, X and II. These factors, in addition to Factor IX, are affected by coumarin anticoagulants. There are several modifications of the Quick one-stage prothrombin time and the physician should become familiar with the specific method used in his laboratory.

Administration of COUMADIN should be gauged according to prothrombin time determinations by a suitable method. The blood prothrombin time should usually be determined daily after the administration of the initial dose until prothrombin time results stabilize in the therapeutic range. Intervals between subsequent prothrombin time determinations should be based upon the physician's judgment of the patient's reliability and response to warfarin in order to maintain the individual within the therapeutic range. Acceptable intervals for prothrombin time determinations have usually fallen within the range of one to four weeks. Satisfactory levels for maintenance of therapeutic anticoagulation are 1½ to 2½ times the normal prothrombin time (e.g. 18 to 30 seconds, with a control of 12 seconds).

Induction—40 to 60 mg for average adult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Alternatively, the large priming dose may be decreased for all patients to minimize the possibility of excessive increases in prothrombin time. Induction may be initiated with 10 to 15 mg daily and thereafter (usually 2 or 3 days) adjusted according to prothrombin time response. The basis for the no-loading dose regimen is that the depression of Factors II, IX, and X are not accelerated by the administration of a loading dose.

Maintenance—Most patients are satisfactorily maintained at a dose of 2 to 10 mg daily. Flexibility of dosage is provided by breaking scored tablets in half. The individual dose and interval should be gauged by the patient's prothrombin response.

Duration of therapy—The duration of therapy in each patient should be individualized. In general, anticoagulant therapy should be continued until the danger of thrombosis and embolism has passed.

Treatment during dentistry and surgery—The management of patients who undergo dental and surgical procedures requires close liaison between attending physicians, surgeons and dentists. Interruption of anticoagulant therapy may precipitate thromboembolism, and conversely, if anticoagulants are maintained at full doses, some patients may hemorrhage excessively. If it is elected to administer anticoagulants prior to, during, or immediately following dental or surgical procedures, it is recommended that the dosage of COUMADIN (crystalline warfarin sodium) be adjusted to maintain the prothrombin time at approximately 1½ to 2½ times the control level. The operative site should be sufficiently limited to permit the effective use of local procedures for hemostasis including absorbable hemostatic agents, sutures, and pressure dressings if necessary. Under these conditions dental and surgical procedures may be performed without undue risk of hemorrhage.

COUMADIN with Heparin—Since a delay intervenes between the administration of the initial dose and the therapeutic prolongation of prothrombin time, it may be advisable in emergency situations to administer sodium heparin initially along with COUMADIN. The initial dose of heparin and injectable COUMADIN may be administered together in the same syringe. It should be noted that heparin may affect the prothrombin time, and therefore, when patients are receiving both heparin and COUMADIN, the blood sample for prothrombin time determination should be drawn just prior to the next heparin dosage, at least 5 hours after the last intravenous injection or 24 hours after the last subcutaneous injection.

TREATMENT FOR OVERDOSAGE Excessive prothrombinopenia, with or without bleeding, is readily controlled by discontinuing COUMADIN (crystalline warfarin sodium), and if necessary, the oral or parenteral administration of vitamin K_1. The appearance of microscopic hematuria, excessive menstrual bleeding, melena, petechiae or oozing from nicks made while shaving are early manifestations of hypoprothrombinemia beyond a safe and satisfactory level.

In excessive prothrombinopenia with mild or no bleeding, omission of one or more doses of COUMADIN may suffice; and if necessary, small doses of vitamin K_1 orally, 2.5 to 10 mg, will usually correct the problem.

If minor bleeding persists, or progresses to frank bleeding, vitamin K_1 in doses of 5 to 25 mg may be given parenterally. (Please note recommendations accompanying vitamin K preparations prior to use.)

Fresh whole blood transfusions should be considered in cases of severe bleeding or prothrombinopenic states unresponsive to vitamin K_1.

Resumption of COUMADIN administration reverses the effect of vitamin K_1, and a therapeutic hypoprothrombinemia level can again be obtained.

SUPPLIED Tablets: COUMADIN (crystalline warfarin sodium). For oral use, single scored, imprinted numerically with potency as follows: 2 mg lavender, 2½ mg orange, 5 mg peach, 7½ mg yellow, 10 mg white. In bottles of 100 and 1000. Also available in Hospital Unit-Dose blister package of 100.

Injection: Available as single injection units of amorphous warfarin sodium lyophilized for intravenous or intramuscular use in a box of 6 units for use immediately after reconstitution.

50 mg: Unit consists of 1 vial, 50 mg; sodium chloride, 10 mg; thimerosal, 0.2 mg. pH is adjusted with sodium hydroxide; accompanied by a 2 ml ampul Sterile Water for Injection.

Sterile Water for Injection contains no antimicrobial or other substance, and it is not suitable for intravascular injection without first having been made approximately isotonic by the addition of a suitable solute. Use only for reconstitution of the lyophilized product.

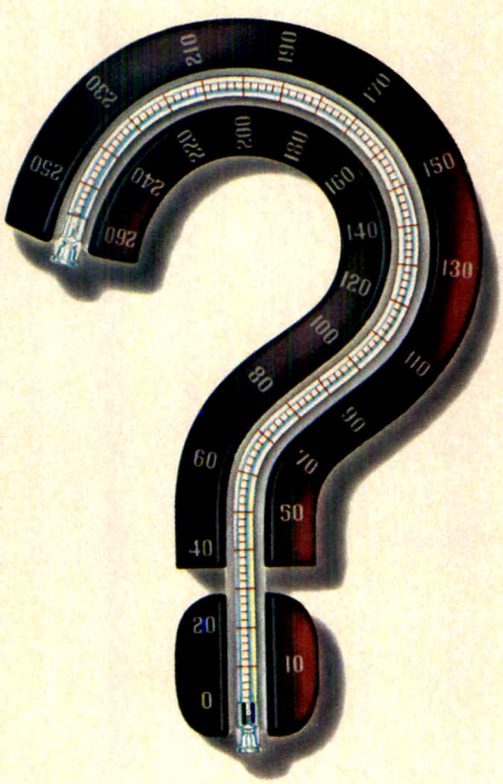
ANSWERS ABOUT ALDOMET®
(METHYLDOPA | MSD)

TO SOME IMPORTANT QUESTIONS ABOUT ANTIHYPERTENSIVE THERAPY.



MSD
MERCK SHARP & DOHME

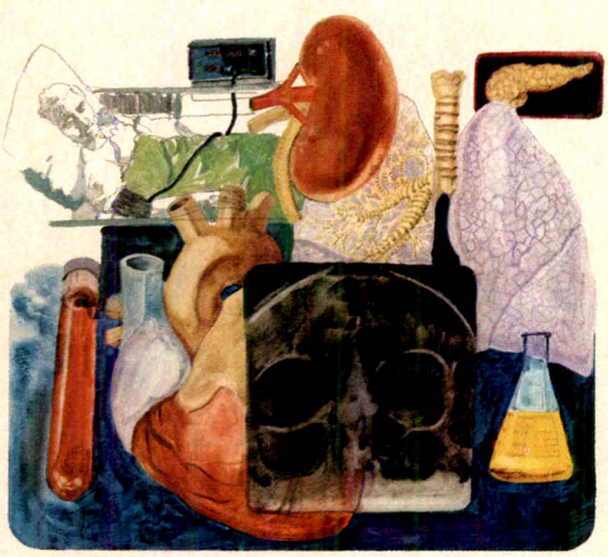
For a brief summary of prescribing information, please see last page of this advertisement.

IN ANTIHYPERTENSIVE THERAPY

...ANSWERS ABOUT

Can an antihypertensive be used in the vast majority of hypertensive patients, including certain patients requiring special considerations?

ALDOMET® CAN
(METHYLDOPA | MSD)



ALDOMET can be used in a wide range of hypertensives, including those with:

- ventricular hypertrophy
- hyperglycemia
- diabetes mellitus
- bronchial asthma
- allergic rhinitis
- hyperuricemia
- gouty arthritis
- sulfonamide hypersensitivity

ALDOMET (Methyldopa, MSD) is contraindicated in active hepatic disease, hypersensitivity to the drug, and if previous methyldopa therapy has been associated with liver disorders.

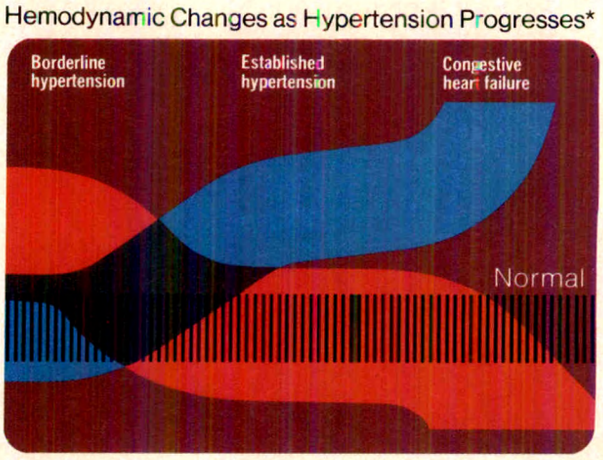
Does an antihypertensive lower blood pressure usually without lowering cardiac output?

ALDOMET DOES
(METHYLDOPA | MSD)

ALDOMET has no direct effect on cardiac function and lowers blood pressure usually without reducing cardiac output. Rather, it appears to reduce peripheral vascular resistance, the most commonly identified hemodynamic variable in hypertension (as hypertension progresses cardiac output tends to decrease and peripheral resistance tends to increase).

Hemodynamic Changes as Hypertension Progresses*



*adapted from Messerli and de Carvalho[1]

This may be particularly important in hypertensives with impaired cardiac function such as those with congestive heart failure.*

*Edema may occur with ALDOMET. This is usually relieved by the use of a diuretic, but if edema progresses methyldopa should be discontinued.

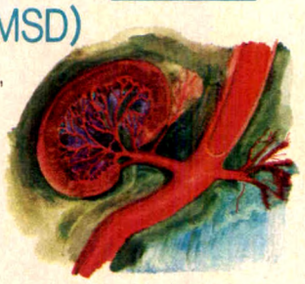
TABLETS: 500 mg, 250 mg, and 125 mg

ALDOMET®
METHYLDOPA | MSD)

The most prescribed nondiuretic antihypertensive in the U.S. today

Can an antihypertensive be effective usually without further reducing renal blood flow?

ALDOMET CAN
(METHYLDOPA | MSD)



Glomerular filtration rate, filtration fraction, and renal blood flow are usually not reduced; therefore, ALDOMET is appropriate for many hypertensive patients with significantly impaired renal function. Since the drug is largely excreted by the kidney, patients with impaired renal function may respond to smaller doses.

Will an antihypertensive generally allow a normal cardiovascular response to exercise?

ALDOMET WILL
(METHYLDOPA | MSD)

Cardiac output and blood pressure normally increase as the physical activities of the patient increase. ALDOMET does not significantly impair normal fluctuations of blood pressure during exercise.[2,3] This can be of importance to active hypertensive patients—such as athletic individuals or persons whose work requires substantial physical effort. With ALDOMET, exercise hypotension rarely occurs.

Sedation, usually transient, may occur during the initial period of therapy or whenever the dose is increased. Headache, asthenia, or weakness may be noted as early and transient symptoms.

Has an antihypertensive shown a proven record in long-term therapy?

ALDOMET HAS
(METHYLDOPA | MSD)

A recent study[4] followed a group of patients on ALDOMET for ten years or more. The results suggest that ALDOMET is a highly effective medication for the long-term management of hypertension.

It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed.

For a brief summary of prescribing information, please see following page.

ALDOMET®
(METHYLDOPA | MSD)

The most prescribed nondiuretic antihypertensive in the U.S. today

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see Warnings); hypersensitivity.

Warnings: It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions.

With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood.

At the start of methyldopa therapy it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first 3 weeks of therapy, occasionally with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur with onset usually in the first 2 to 3 months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever and abnormalities in liver function tests or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients.

Rarely, a reversible reduction of the white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Patients should be followed carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant or intend to nurse requires that anticipated benefits be weighed against possible risks; possibility of fetal injury or injury to a nursing infant cannot be excluded. Methyldopa crosses the placental barrier, appears in cord blood, and appears in breast milk.

Precautions: Should be used with caution in patients with history of previous liver disease or dysfunction (see Warnings). May interfere with measurement of: urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

Adverse Reactions: *Central nervous system:* Sedation, headache, asthenia or weakness, usually early and transient; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression.

Cardiovascular: Bradycardia, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.)

Gastrointestinal: Nausea, vomiting, distention, constipation, flatus, diarrhea, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis.

Hepatic: Abnormal liver function tests, jaundice, liver disorders.

Hematologic: Positive Coombs test, hemolytic anemia. Leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells, and rheumatoid factor.

Allergic: Drug-related fever, lupus-like syndrome, myocarditis.

Other: Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, impotence, decreased libido, dermatologic reactions including eczema and lichenoid eruptions, mild arthralgia, myalgia.

Note: Initial adult dosage should be limited to 500 mg daily when given with antihypertensives other than thiazides. Tolerance may occur, usually between second and third months of therapy; increased dosage or adding a diuretic frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

How Supplied: Tablets, containing 125 mg methyldopa each, in bottles of 100; Tablets, containing 250 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 1000; Tablets, containing 500 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 500.

Infiltrative Cardiomyopathy With Conduction Disease and Ventricular Arrhythmia: Electrophysiologic and Pathologic Correlations

SAROJA BHARATI, MD, FACC
MAURICE LEV, MD, FACC*
PABLO DENES, MD, FACC
JAMES MODLINGER, MD, FACC
CHRISTOPHER WYNDHAM, MD, FACC
ROBERT BAUERNFEIND, MD

KENNETH M. ROSEN, MD, FACC

Chicago, Illinois

Two cases are described, one of cardiac sarcoidosis and another of primary cardiac amyloidosis, in which correlation was made between electrophysiologic and postmortem conduction system studies. In Case 1 the electrocardiogram revealed right bundle branch block with first degree and intermittent third degree atrioventricular (A-V) block and recurrent unifocal paroxysmal ventricular tachycardia. Electrophysiologic studies disclosed normal sinus rhythm with prolonged A-H (175 ms) and H-V (60 ms) intervals and extrastimulus induction of repetitive ventricular firing. Postmortem examination revealed a sarcoid aneurysm of the posterior left ventricle and granulomatous infiltration of the A-V node, His bundle and bundle branches. In Case 2 the electrocardiogram revealed sinus bradycardia, a prolonged S-T interval and recurrent ventricular fibrillation. Electrophysiologic studies demonstrated a prolonged sinus nodal recovery time (6,080 ms) and H-V (85 ms) interval. Postmortem examination revealed marked amyloid infiltration of the sinoatrial node, atria, proximal bundle branches and left and right ventricular myocardium.

There was thus excellent correlation between electrophysiologic and pathologic findings. These cases indicate the importance of making a clinical diagnosis of the disease that might in some cases allow specific therapeutic intervention in addition to antiarrhythmic therapy.

Conduction defects, ventricular arrhythmia and sudden death are known complications of infiltrative cardiomyopathy. Despite the frequency of these complications, there are few data concerning results of electrophysiologic testing and correlation with pathologic findings in patients with this disorder. In this report, we describe in detail electrocardiographic, electrophysiologic and pathologic findings (including results of serial section studies of the conduction system) in two patients, one with cardiac sarcoidosis and the other with cardiac amyloidosis. Both patients manifested conduction defects and severe ventricular arrhythmia. There was a close correlation among the electrocardiographic, electrophysiologic and pathologic findings.

Case Reports

Case 1 (Cardiac Sarcoidosis)

The patient was a 34 year old man of Italian ancestry who was in good health until June 1973, when he was admitted to a hospital in California with recurrent episodes of fever and abdominal pain. An unsubstantiated diagnosis of familial Mediterranean fever was made. In April 1974, he was readmitted because of vertigo and a syncopal episode. Results of neurologic evaluation were normal. In May 1974, the syncopal episodes recurred, and the patient was readmitted. He was noted to have bradycardia and the electrocardiogram revealed atrioventricular (A-V) block (see later). Initially, a temporary pacemaker was inserted and subsequently a permanent transvenous demand pacemaker implanted. The

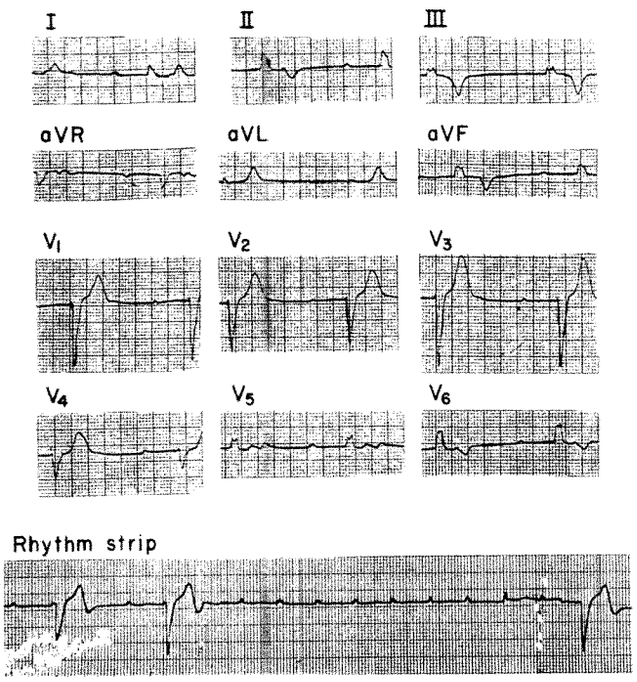

FIGURE 1. Case 1. Electrocardiograms demonstrating 2:1 atrioventricular (A-V) block with a P-R interval of 0.44 second and QRS complexes revealing left bundle branch block. The rhythm strip demonstrates a prolonged asystolic period due to paroxysmal atrioventricular block.

patient then became asymptomatic until November 1974, when he noticed episodes of "fast heart beating." These episodes were short-lived (15 minutes) and self-limited. The patient underwent dynamic electrocardiographic monitoring that revealed short episodes of wide QRS tachycardia (rate 180/min).

On November 15, 1974, after a sustained paroxysmal tachycardia developed, the patient was admitted to the University of Illinois Hospital. On admission he was found to have ventricular tachycardia (see later), that failed to respond to intravenous administration of lidocaine and disopyramide; cardioversion to sinus rhythm was accomplished with direct current electric shock. The physical examination after cardioversion revealed a blood pressure of 110/80 mm Hg, a pulse rate of 80 beats/min and normal carotid pulses. Cardiovascular examination revealed a normal first heart sound and a widely split second heart sound that varied with respiration. There were no murmurs or gallops and no other abnormal physical findings.

Diagnostic cardiac catheterization on November 25 revealed normal pressures in all cardiac chambers with no gradient across the valves. The cardiac output was normal. Left ventricular angiography revealed a well delineated area of hypokinesia of the posterior left ventricle. The left ventricular ejection fraction was decreased (0.40). Coronary angiograms revealed a normal right and left coronary system.

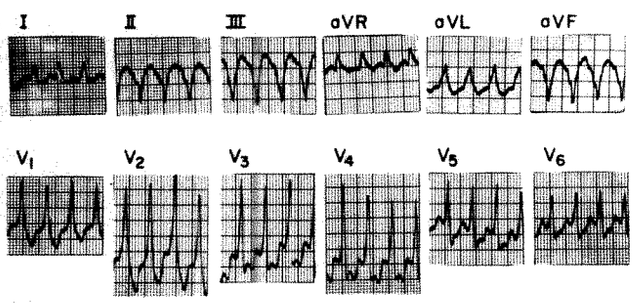

FIGURE 2. Case 1. Electrocardiogram demonstrating paroxysmal sustained ventricular tachycardia with a rate of 187 beats/min. The right bundle branch block pattern with abnormal left axis deviation suggests ventricular tachycardia originating from the posterior left ventricle.

Review of Electrocardiograms

The first electrocardiogram available for review, obtained in December 1971 revealed normal findings: normal sinus rhythm at a rate of 74/min, a P-R interval of 0.16 second, a QRS duration of 0.08 second and a mean frontal axis of 80°.

Electrocardiograms during the hospitalization for syncope (May 1974) revealed the following rhythm disturbances: (1) first degree A-V block (P-R interval 0.38 second) with complete right bundle branch block. (2) 2:1 A-V block with left bundle branch block (Fig. 1). (3) Paroxysmal A-V block with prolonged asystole (Fig. 1). Subsequent electrocardiograms showed the presence of a demand right ventricular pacemaker with occasional conducted beats showing first degree A-V block (P-R interval 0.28 second) and right bundle branch block with a mean frontal QRS axis of +90°.

The electrocardiogram taken on admission to the University of Illinois Hospital (November 15, 1974) revealed a wide QRS tachycardia (rate 187/min), right bundle branch block (with a monophasic R wave in lead V_1 and an Rs wave in lead V_6) and a frontal plane axis of −60° (with QS complexes in leads II, III and aVF) (Fig. 2). An esophageal recording revealed the presence of A-V dissociation with an atrial rate of 110/min. The electrocardiographic diagnosis was posterior left ventricular tachycardia. Subsequent electrocardiograms during the hospital stay revealed sinus rhythm with first degree A-V block and right bundle branch block (Fig. 3). The demand ventricular pacemaker was functioning adequately with ventricular capture beats during periods of sinus slowing.

Electrophysiologic Studies

On November 27, electrophysiologic studies were performed using previously described catheter techniques.[1] A hexapolar catheter was introduced through the right basilic vein and

TABLE 1

Refractory Periods in Cases 1 and 2

	Case 1		Case 2	
	Sinus Rhythm (640 ms)	Paced Rhythm (470 ms)	Sinus Rhythm (660 ms)	Paced Rhythm (470 ms)
Atrial ERP	230	210	420	225
Atrial FRP	290	230	530	330
A-V nodal ERP	290	230	530	390
A-V nodal FRP	390	370	400	340
HPS ERP	390	370	. . .	. . .
RV ERP	240	. . .	240	. . .

ERP = effective refractory period; FRP = functional refractory period; HPS = His-Purkinje system; RV = right ventricular.

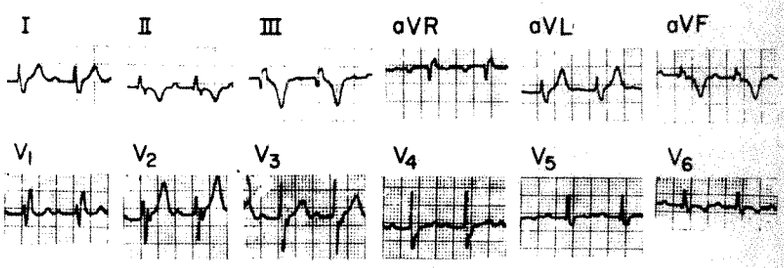

FIGURE 3. Case 1. Electrocardiogram demonstrating sinus rhythm, first degree atrioventricular block (P-R interval 0.26 second) and right bundle branch block with a normal axis.

advanced to the right ventricular apex. The proximal four electrodes were positioned against the right atrial wall and were used for stimulation and recording from the high right atrium. The distal pair of electrodes were used for right ventricular stimulation. Refractory periods were measured during sinus rhythm (cycle length 670 ms) and with atrial pacing (cycle length 470 ms) utilizing the atrial extrastimulus technique.[2]

Control rhythm during electrophysiologic study was sinus with intact A-V conduction and right bundle branch block. Both the A-H and H-V intervals were prolonged (175 and 60 ms, respectively); the P-A interval was normal (20 ms) (Fig. 4). With incremental atrial pacing, 1:1 A-V conduction was maintained to a paced rate of 180/min. Wenckebach periods proximal to the H potential were noted at a paced atrial rate of 190/min. The A-V conduction curves generated with the atrial extrastimulus technique were normal during both sinus rhythm and atrial pacing. Conduction at both cycle lengths was limited by atrial refractoriness. All refractory periods were normal (Table I). The sinus nodal recovery time and sinoatrial conduction time were normal (780 and 115 ms, respectively).[1,3]

Ventricular incremental pacing at rates of 100 to 130/min revealed absence of ventriculoatrial conduction. Ventricular coupled pacing during sinus rhythm was performed from the right ventricular apex. At V_1-V_2 intervals of 280 to 340 ms single ventricular reentrant complexes, similar in configuration to those of the spontaneous ventricular tachycardia, were recorded. At a V_1-V_2 interval of 330 ms, one 19 beat episode of ventricular tachycardia was observed (QRS pattern of left bundle branch block).

Follow-up

On discharge from the University of Illinois Hospital the patient was receiving procainamide (500 mg every 6 hours). This drug was subsequently changed to propranolol (120 mg/day) because of recurrent episodes of ventricular tachycardia observed during exercise. On June 25, 1976 while riding a bicycle, he collapsed and died suddenly. Routine ambulatory electrocardiographic monitoring had been performed on this day, and revealed an episode of ventricular tachycardia degenerating into fatal ventricular fibrillation.

Autopsy Findings

Aside from the findings in the heart, the pathologic diagnosis was sarcoidosis of the anterior mediastinal and paratracheal lymph nodes. No evidence of sarcoidosis was found in any of the other organs.

Heart: Gross Examination

The heart weighed 359 g. The left atrium and left ventricle were slightly hypertrophied, and the latter was slightly enlarged. In the posterobasal part of the ventricular septum extending into the posterior basal wall adjacent to the mitral valve there was an aneurysm (Fig. 5). The endocardium lining the aneurysm was thickened. The pars membranacea and the aortic-mitral anulus were thickened and included in the aneurysm. The myocardium of the basal part of the posterior wall was replaced by greyish-white tissue (Fig. 5). The right aortic cusp was markedly fenestrated. There was mild arteriosclerotic narrowing of the anterior and posterior descending coronary arteries. The endocardium of the sinus of the right

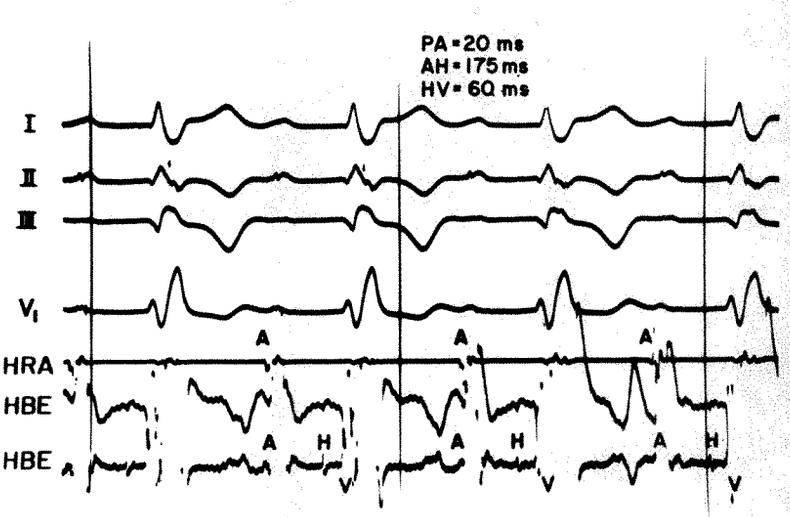

FIGURE 4. Case 1. Conduction intervals during sinus rhythm. Shown are leads I, II, III, V_1, high right atrial electrogram (HRA) and two His bundle electrograms (HBE). Note the prolonged A-H and H-V and normal P-A intervals. Paper speed is 100 mm/s; time lines are at 1 second intervals.

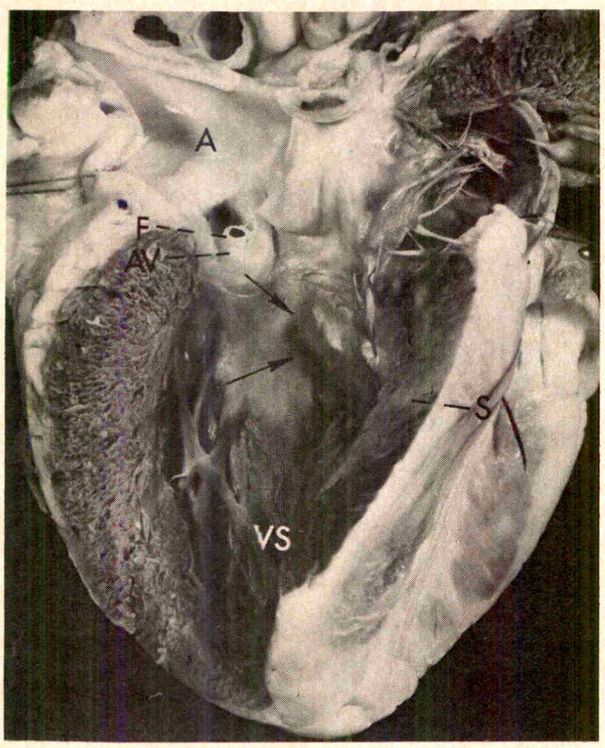

FIGURE 5. Case 1. View of the outflow tract of the left ventricle and of the ascending aorta (A). Note the aneurysm (**arrows**) in the basal part of the posterior ventricular septal wall and posterior wall, with sarcoid (S) in the posterior wall. AV = aortic valve; F = fenestration; VS = ventricular septum.

FIGURE 6. Case 1. Atrioventricular (A-V) node and its approaches. Note the sarcoid in the approaches (Ap) to and in the periphery of the A-V node (N). (Hematoxylin-eosin ×80, reduced by 30 percent.)

ventricle close to the apex showed a fibrous tubular formation indicating long-standing pacemaker presence.

Histologic Examination

Methods: The sinoatrial (S-A) node and its approaches, the atrioventricular (A-V) node, bundle of His and bundle branches up to the level of the moderator band were serially sectioned, and every 10th section was retained. The atrial preferential pathways were serially sectioned and every 40th section was retained. The remainder of the heart was cut into blocks, and two sections were taken from each block. Consecutive sections of the conduction system were stained with hematoxylin-eosin, Weigert-van Gieson and Gomori trichrome stains. Alternate sections of the remainder of the heart were stained with hematoxylin-eosin and Weigert-van Gieson stains. In this manner 1,416 sections were examined.

Findings:

S-A node: This was normal.

Approaches to S-A node: Moderate involvement by sarcoid was present.

Atrial preferential pathways: These were only slightly involved by sarcoid.

Approaches to A-V node: Almost complete replacement of muscle by sarcoid was noted, and there was marked fibrosis (Fig. 6). The ramus septi fibrosi was narrowed.

A-V node: This was likewise markedly replaced by sarcoid, with accompanying fibrosis (Fig. 6).

A-V bundle, penetrating portion: Marked fibrosis was present with moderate involvement by sarcoid.

A-V bundle, branching portion: There was marked fibrosis, with moderate involvement with sarcoid.

Left bundle branch: The beginning and most of its extent showed marked replacement by sarcoid tissue (Fig. 7, left).

Right bundle branch: In the first portion, there was marked fibrosis (Fig. 7, left). The second portion was replaced by sarcoid; the third portion was normal.

Ventricular septum: The posterior portion of the summit was markedly replaced by sarcoid tissue accompanied by connective tissue (Fig. 7, right). This was less severe anteriorly. The more apical portion showed moderate involvement with sarcoid.

Left ventricle. Anterior wall: This was free of sarcoid tissue.

Left ventricle. Posterior wall: In the greyish-white area seen grossly, there was almost complete involvement by sarcoid with marked fibrosis and hyalinization.

Right ventricle: This was moderately involved with sarcoid.

Sarcoid tissue: This consisted of single and conglomerate granulomas. The latter contained giant cells of the Langhans type, many with asteroid bodies, accompanied by numerous lymphocytes and epithelioid cells. Severe fibrosis accompanied many of the lesions.

Case 2 (Cardiac Amyloidosis)

The patient was a 53 year old man who was in good health until 1975, when he noted the gradual onset of dyspnea on exertion. One year later he noted chest pain on exertion. Coronary angiography at that time revealed normal coronary

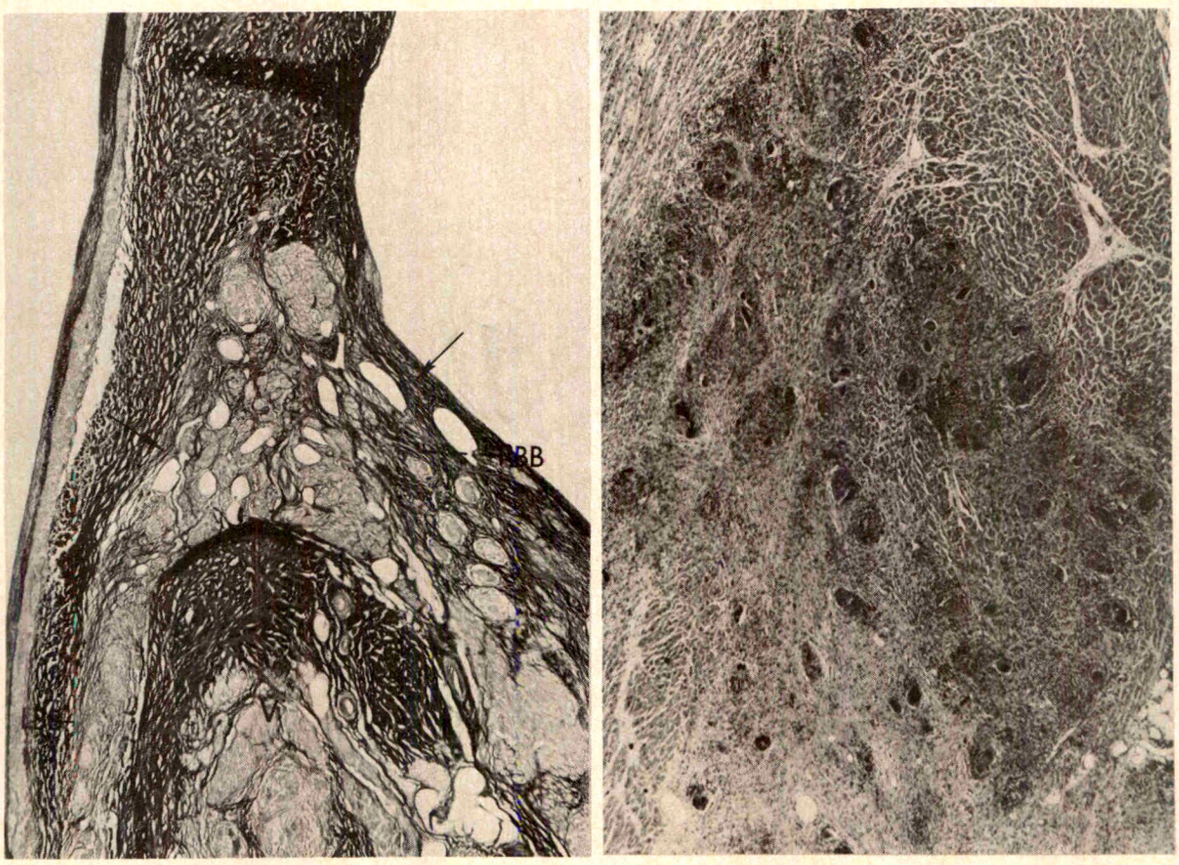

FIGURE 7. Case 1. **Left,** bifurcation of atrioventricular bundle **(arrows).** Note the complete obliteration of the right side of the bifurcation (beginning of the right bundle branch [RBB]) by fibrosis, and the marked involvement of the beginning of the left bundle branch (LBB) by sarcoid. The summit of the ventricular septum (V) is involved in sarcoid and fibrosis. (Weigert-van Gieson ×30, reduced by 30 percent.) **Right,** posterior wall of the left ventricle involved in sarcoid. (Hematoxylin-eosin ×30, reduced by 30 percent.)

arteries and mild left ventricular dysfunction. During a treadmill exercise test, premature ventricular complexes were detected, and he was given propranolol. In January 1977, he suddenly experienced blurred vision, slurred speech and right-sided weakness that resolved within a period of 24 hours. Results of neurologic examination were normal. One month later, signs and symptoms of overt congestive heart failure developed. Administration of propranolol was discontinued, maintenance therapy with digitalis was instituted and treatment with procainamide (2 g/day) was begun. On March 22 he had a syncopal attack accompanied by generalized seizures and urinary incontinence. He was admitted to a community hospital where recurrent attacks of ventricular tachycardia and fibrillation were documented. These were refractory to multiple antiarrhythmic drugs.

On March 31 he was transferred to the University of Illinois Hospital for further evaluation. On admission, physical examination revealed a blood pressure of 110/70 mm Hg, pulse rate of 95 beats/min, mild jugular venous distension and normal carotid pulses. Cardiac examination revealed an active precordium with the left ventricular impulse being diffuse and displaced laterally. The first heart sound was soft, the second heart sound single, and there was a ventricular gallop sound. The lungs were clear, the liver was not enlarged and there was no edema. The chest roentgenogram revealed cardiomegaly with prominent pulmonary vasculature. After admission, administration of all drugs was discontinued while the patient was observed. On April 4 several episodes of ventricular tachycardia and fibrillation developed necessitating multiple direct current cardioversions. After cardioversion, he had prolonged periods of asystole and required temporary pacing.

Diagnostic cardiac catheterization and electrophysiologic study (see later) were performed on April 5. He had single vessel coronary artery disease (60 percent narrowing of the luminal diameter of the marginal branch of the left circumflex artery), mild left ventricular dysfunction (end-diastolic pressure 15 mm Hg) with restrictive cardiomyopathic pattern and depressed cardiac index (2.2 liters/min per M^2). Left ventricular angiography revealed mild mitral regurgitation, with no segmental areas of dyskinesia. The ejection fraction was 40 percent. After cardiac catheterization, and despite treatment with temporary pacing and antiarrhythmic drugs, recurrent episodes of ventricular tachycardia and fibrillation developed. A permanent pacemaker was implanted, but he became progressively confused, dyspneic and hypotensive. He died on April 10 with ventricular fibrillation.

Review of Electrocardiograms

The electrocardiogram on admission revealed paroxysmal atrial tachycardia (atrial rate 186 beats/min) with 2:1 A-V block (ventricular rate 93/min). The mean frontal QRS axis was −20° and there was low voltage of the QRS complex in the standard and augmented limb leads. There were QS com-

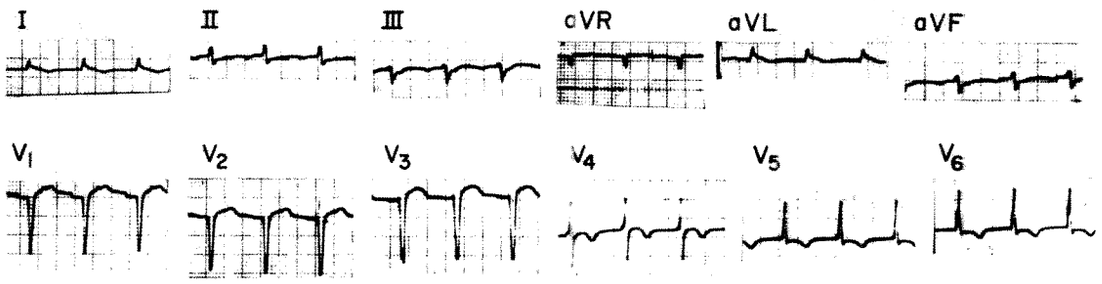

FIGURE 8. Case 2. Admission electrocardiogram demonstrating paroxysmal atrial tachycardia with 2:1 atrioventricular block (atrial rate 186 and ventricular rate 93 beats/min). The P waves are best visualized in lead V_1. Also note low voltage in the limb leads, the QS complexes in leads V_1 and V_2 and nonspecific ST-T wave changes.

plexes in leads V_1 and V_2, as well as nonspecific S-T and T wave changes (Fig. 8). Episodes of paroxysmal atrial tachycardia with 2:1 block alternated with periods of sinus rhythm with sinus rates of 50 to 90 beats/min.

Multiple episodes of ventricular flutter were recorded that degenerated quickly into ventricular fibrillation (Fig 9). These necessitated emergency direct current cardioversion.

Electrophysiologic Studies

Electrophysiologic studies were performed while the patient had sinus rhythm. The P-A interval was 50 ms (prolonged), the A-H interval 110 ms and the H-V interval 85 ms (prolonged).[1] Sinus nodal recovery time at a paced rate of 130/min averaged 1,470 ms.[1] However, very prolonged recovery times up to 6,080 ms were recorded (Fig. 10).

With incremental atrial pacing, intact A-V conduction was maintained up to a paced rate of 160/min. A-V nodal Wenckebach periods were noted at a paced rate of 170/min. Atrial extrastimulus testing during both sinus rhythm and atrial driving revealed normal A-V conduction curves. Atrial effective and functional refractory periods were markedly prolonged; all other refractory periods were normal (Table I).[2]

Ventricular incremental pacing at rates of 100 to 250/min revealed absent ventriculoatrial conduction. Ventricular extrastimulus testing (including S_2-S_3 stimulation) during sinus rhythm and a paced ventricular cycle length of both 500 and 360 ms failed to induce either ventricular tachycardia or repetitive ventricular firing.

Autopsy Findings

Aside from the findings in the heart, the pathologic diagnoses were: (1) amyloidosis with involvement of the liver, tongue, skeletal muscle, esophagus and vessels of the lungs, stomach, colon and adrenal glands; (2) pulmonary edema; (3) collapse of lower lobes of lungs; (4) chronic passive hyperemia of the liver; (5) chronic pyelonephritis; and (6) acute hemorrhagic cystitis. There was no evidence of multiple myeloma.

Heart: Gross Examination

The heart weighed 770 g. All chambers were hypertrophied and enlarged. Hemorrhagic zones were noted in the region of the S-A node and in the endocardium of the right atrium. Focal areas of endocardial thickening and whitening were noted in the left atrium and ventricle. A thrombus was present in the right atrial appendage.

Microscopic Examination

Methods: The S-A node and its approaches, the A-V node and its approaches, the A-V bundle and bundle branches up to the region of the moderator band were serially sectioned and every 10th section was retained. The atrial preferential pathways were serially sectioned and every 40th section was retained. The remainder of the heart was cut into blocks and two sections were taken from each block. Consecutive sections of the conduction system were stained with hematoxylin-eosin, Weigert-van Gieson and Gomori trichrome stains. Alternate sections of the remainder of the heart were stained with hematoxylin-eosin and Weigert-van Gieson stains. In addition, sections were stained with methyl violet for metachromasia and with Congo red, and tested for green birefringence with the polarized microscope to detect amyloid. In this manner 1,232 sections were examined.

Findings: *S-A node:* A slight infiltration of amyloid was present. The arterioles however showed considerable amyloid. The cells of the upper and lower poles were the seat of acute degeneration. The periphery of the node showed marked fatty infiltration.

Approaches to the S-A node: There was marked diffuse infiltration of amyloid in the myocardium (Fig. 11, left). The epicardium and endocardium were similarly infiltrated, as were all the vessels. Marked fatty infiltration and moderate necrosis of the myocardium were also present. Narrowing of vessels was present only at the anteriolar level. There was a slight infiltration of mononuclear cells in the epicardium.

Atrial preferential pathways: Marked infiltration of amyloid in the myocardium and endocardium with severe degeneration of muscle cells and atrophy of muscle cells was present (Fig. 11, right). In addition, there was acute focal necrosis of muscle cells. The arterioles were infiltrated with amyloid and the small arterioles were narrowed.

Approaches to A-V node: Marked infiltration of amyloid was present with atrophy of muscle cells. There was marked arteriolosclerosis with amyloid infiltration.

A-V node: The periphery of the node showed marked fatty infiltration with acute focal necrosis, and moderate amyloid infiltration that involved fat tissue as well. There was slight focal infiltration with mononuclear cells.

A-V bundle, penetrating portion: The periphery was moderately infiltrated with amyloid. There was slight to moderate fatty infiltration. An occasional focus of fibrosis was present.

A-V bundle, branching portion: The periphery showed marked amyloid infiltration. The cells of the bundle were smaller than normal. The vessels showed amyloid.

Left bundle branch: Marked infiltration with amyloid (Fig. 12, left) with shrinkage of cells and loss of cells was present. The cells that remained were smaller than Purkinje cells.

Right bundle branch: Severe amyloid infiltration, fatty infiltration and marked shrinkage of cells were evident in the first portion and in the beginning of the second portion (Fig.

12, right). Involvement was less in the remainder of the second and the third portions.

Left ventricle: The myocardium was markedly and diffusely involved with amyloid in both the anterior and the posterior walls as well as in the septum.

Right ventricle: Involvement was less than in the left ventricle.

Atria: The atrial myocardium and endocardium were involved with amyloid.

Discussion

Infiltrative disease of the heart such as sarcoidosis[4–18] and amyloidosis[19–36] with particular involvement of the conduction system resulting in cardiac arrhythmias has often been reported. However, very few cases have been described in which there has been careful correlation of electrophysiologic and pathologic findings. Takagi et al.[15] reported the only case of cardiac sarcoidosis and Rosen et al.[30,32] reported three cases and Bharati et al.[34] one case of cardiac amyloidosis with such correlation.

Electrophysiologic-pathologic correlations in Case 1: In Case 1, electrocardiograms and electrophysiologic studies suggested significant conduction disease. There was A-V nodal dysfunction as manifested by a prolonged A-H interval (which appears primarily responsible for electrocardiographically diagnosed first degree A-V block). However, studies of A-V nodal pacing response and refractory period yielded normal findings. There was definite dysfunction in the His-Purkinje system as manifested by electrocardiographically diagnosed right bundle branch block and by H-V prolongation (suggesting conduction delay in either the distal His bundle or left bundle branch system).

Because His bundle electrograms were not recorded during the episodes of A-V block in 1974, a definite site of block could not be determined. However, the occur-

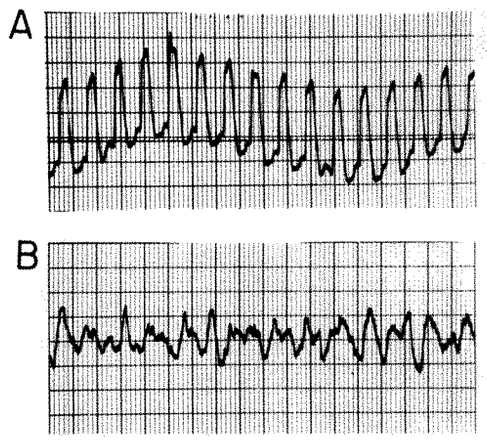

FIGURE 9. Case 2. Rhythm strips demonstrating ventricular flutter (**A**) and ventricular fibrillation (**B**).

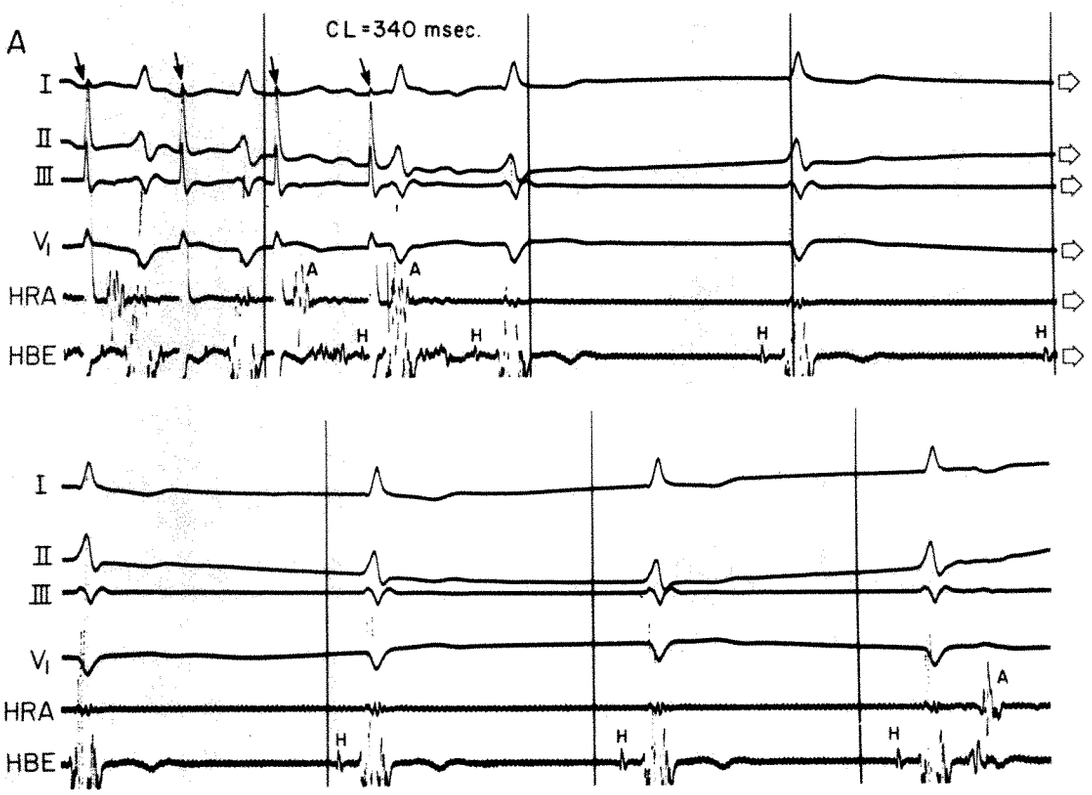

FIGURE 10. Case 2. Continuous rhythm strips showing sinus nodal recovery time. The recovery time at a paced atrial cycle length of 340 ms is greater than 5 seconds (note first atrial escape at end of the **bottom strip**). Atrioventricular (A-V) junctional escape with A-V junctional rhythm occurs well before the occurrence of the sinus or the atrial escape. Time lines are at 1 second intervals. Abbreviations as in Figure 4.

(Hematoxylin-eosin ×30, reduced by 31 percent.)

rence of right bundle branch block with intact A-V conduction, 2:1 A-V block, left bundle branch block and the prolonged paroxysm of A-V block suggested that the episode of A-V block was within the bundle branches (bilateral bundle branch block). It is not clear why A-V block was a clinical problem for only a relatively short period in the patient's life. There was no subsequent evidence of recurrence of second or third degree A-V block in any recorded electrocardiograms.

On the basis of these findings, one would predict widespread conduction disease involving the A-V node, possibly the His bundle and definitely both bundle branches (with the right bundle branch possibly being more severely involved than the left). There was no electrocardiographic or electrophysiologic evidence of sinus node or atrial disease. There was also evidence of significant electrophysiologic involvement of the left ventricle. Ventricular tachycardia had a QRS pattern of right bundle branch block with left axis deviation, suggesting an origin of ventricular tachycardia from the posterior left ventricle. This was totally consistent with the left ventricular angiographic findings of a hypokinetic posterior left ventricle in the absence of significant obstructive coronary disease. Electrophysiologic study did not allow replication of this tachycardia; therefore, a specific mechanism was not delineated. The paroxysmal onset and offset of this ventricular tachycardia was consistent with it being reentrant. The 19 beat episode of ventricular tachycardia with a left bundle branch block pattern, initiated during electrophysiologic study with the ventricular extrastimulus technique, was consistent with a reentrant tachycardia originating in the right ventricle (thus suggesting right ventricular involvement as well). It is not known whether this ventricular tachycardia occurred spontaneously.

In correlating these electrophysiologic data with the pathologic findings, it must be noted that the electrophysiologic studies were performed in November 1974 and the patient died in June 1976. Thus the pathologic changes may be more extensive than the electrophysiologic studies indicated. Nevertheless; there is good correlation between the electrophysiologic and pathologic findings. There was moderate involvement by sarcoid of the approaches to the S-A node and marked involvement of the approaches to the A-V node, the A-V node, the His bundle and both bundle branches by sarcoid. As indicated electrophysiologically, there was little disease in the S-A node and the atrial preferential pathways. However, the approaches to the S-A node revealed more disease than expected, and this difference may be related to further evolution in the 2 year period

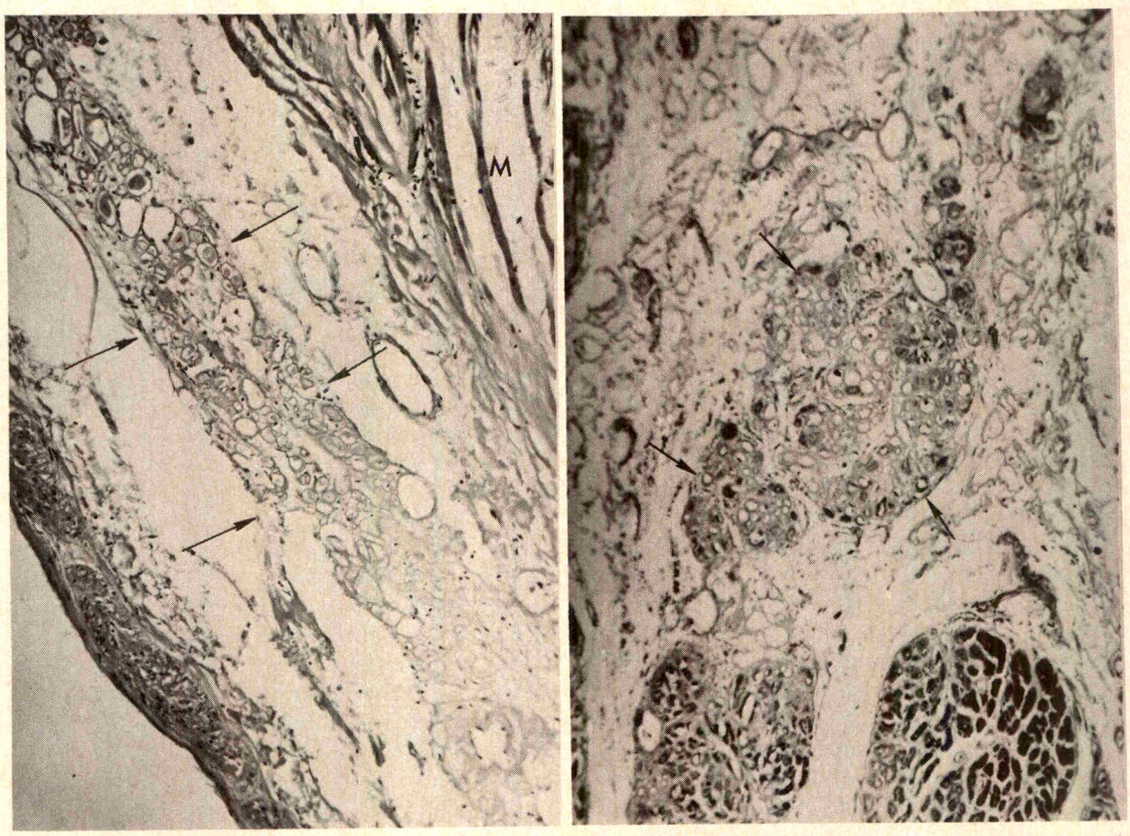

FIGURE 12. Case 2. **Left,** left bundle branch. Note the amyloid infiltration in the left bundle branch (**arrows**) with marked destruction of muscle cells (M). (Hematoxylin-eosin ×80, reduced by 31 percent.) **Right,** right bundle branch. Note the marked infiltration of the right bundle branch (**arrows**) by amyloid with almost complete destruction. between the time of electrophysiologic study and the time of death. The replacement of the posterior basal septal and posterior wall of the left ventricle by sarcoid fits in well with the diagnosis of posterior left ventricular tachycardia.

Electrophysiologic-pathologic correlations in Case 2: Multiple conduction abnormalities were delineated in this patient. Sinus nodal function was abnormal, as manifested by prolonged asystole after cardioversion (this finding is also consistent with a decrease in automaticity throughout the heart) and by very prolonged sinus nodal recovery time. Atrial disease was manifested by clinically observed paroxysmal atrial tachycardia (with block), a prolonged P-A interval and markedly prolonged atrial refractoriness. A-V nodal function appeared adequate on the day of electrophysiologic study. His-Purkinje function was abnormal, as manifested by a prolonged H-V interval with narrow QRS complexes. The prolonged H-V interval therefore reflected either conduction delay within the His bundle or bilateral equivalent bundle branch delays. Ventricular electric dysfunction was manifested by recurrent episodes of ventricular flutter and fibrillation. The lack of ventricular repetitive firing with extrastimulus testing was surprising in view of the patient's demonstrated propensity to ventricular flutter and fibrillation. The ventricular electric dysfunction was also consistent with restrictive cardiomyopathy, as diagnosed from cardiac catheterization data.

The electrophysiologic studies in this case were performed shortly before death. Hence the correlation with pathologic findings would be expected to be more exact than that in Case 1. Consistent with the electrophysiologic findings, there were marked changes throughout the conduction system. Although the S-A nodal parenchyma did not show much change, the approaches to the S-A node were markedly involved by amyloid infiltration and with muscle degeneration as were the atrial preferential pathways and the approaches to the A-V node. Only the periphery of the A-V node was infiltrated with amyloid. Marked involvement of the bundle branches was present with amyloid infiltration and destruction of parenchyma.

Cardiac sarcoidosis: In sarcoidosis the heart is involved in about 13 to 25 percent of cases.[8,17,18] Cardiac sarcoidosis is usually associated with lymph node and frequently with lung involvement. It often leads to heart block,[4,17,18] ventricular arrhythmias[3,8,17] and sudden death.[7,8,12,16,17] The posterior wall of the left ventricle is a site of predilection for sarcoid, and aneurysm of the left ventricle has been reported.[17] The atria are relatively spared in sarcoidosis. Few conduction system

studies have been performed in this disease.[16] Those available have revealed involvement of the A-V node and bundle.

Cardiac amyloidosis: Amyloidosis may be primary, or secondary to other chronic diseases. When it is primary, the disease, especially the senile form, may be localized only to the heart.[31] Whether it is primary or secondary, the heart is involved in about 70 percent of cases.[27] The atria (especially the left) are more involved than the ventricles.[31] The amyloid infiltration compresses ventricular muscle cells, frequently causing congestive heart failure. All parts of the conduction system may be extensively involved. According to James,[26] the S-A node is especially infiltrated with amyloid. The reported conduction disturbances[21–35] include atrial fibrillation, sinus arrest, first degree A-V block, bundle branch block, advanced and complete A-V block and serious ventricular arrhythmia. Our Case 2 is the first case associated with ventricular tachycardia to be reported.

Clinical implications: These two cases of infiltrative cardiomyopathy have several clinical features in common. Both patients manifested serious conduction defects (atrioventricular and intraventricular in Case 1, and sinoatrial in Case 2), as well as ventricular arrhythmia. In both cases, the ventricular arrhythmia was serious, being the direct cause of death in Case 1 and an important contributory cause in Case 2. In both cases, arrhythmias were the dominant feature of the disease process and the reason for referral to our medical center. Cardiac catheterization in both cases demonstrated myocardial dysfunction (localized in Case 1 and generalized in Case 2). Extracardiac biopsy could have provided a definitive diagnosis in both cases; a scalene node biopsy probably would have been positive for sarcoid in Case 1, and biopsy of the rectum, gingiva or tongue would almost certainly have been positive for amyloid in Case 2. Catheter endocardial biopsy in both cases would probably also have provided definitive histologic diagnosis. The premortem demonstration of sarcoidosis in Case 1 would have led to consideration of use of corticosteroids, which might have had a benevolent effect on this patient's clinical course. It is doubtful that any specific intervention would have changed the course of Patient 2.

It is our opinion that these cases support the value of extensive noninvasive and invasive diagnostic studies in patients with serious, apparently primary, arrhythmia. In selected patients with arrhythmia or conduction system disease, either extracardiac or cardiac biopsy (endocardial or open), would seem appropriate in an attempt to establish definitive diagnosis of a specific cardiomyopathic process. This procedure would be particularly important in young patients with widespread conduction disease and evidence of localized or generalized ventricular involvement. Such a demonstration might allow specific therapeutic interventions in addition to the usual antiarrhythmic therapy.

Cough-Facilitated Conversion of Ventricular Tachycardia

JEANNE Y. WEI, MD, PhD
H. LEON GREENE, MD, FACC
MYRON L. WEISFELDT, MD, FACC

Baltimore, Maryland

Coughing has been shown to be helpful in altering the bradycardia and hypotension that may occur after intracoronary injections of contrast medium and can enable a patient to maintain consciousness during episodes of ventricular fibrillation and asystole. This report describes a patient with ischemic heart disease in whom 33 episodes of drug-refractory ventricular tachycardia were converted to normal sinus rhythm after abrupt forceful coughs were performed on command. When the patient was unable to cough as directed, external electric countershock was necessary to terminate the arrhythmia. These findings suggest that the cough may in isolated cases be effective in the conversion of potentially fatal ventricular tachyarrhythmias.

The current therapy for ventricular tachycardia frequently involves electric conversion, which may be accomplished with direct current external countershock,[1] rapid atrial or ventricular stimulation with a pacemaker[2] or administration of timed intraventricular electric stimuli.[3] Intravenous drugs are also effective.[4] Another mode of treatment consists of mechanical stimulation, either by a direct blow to the chest wall (chest thump)[5] or by stimulation of the endocardial surface during manipulation of the catheter or pacemaker wire.[6] A fourth method, to be discussed, may be the cough. Coughing is known to aid in the conversion of the bradycardia and hypotension observed after intracoronary injection of contrast medium,[7,8] and it can temporarily enable a patient to maintain consciousness during episodes of ventricular fibrillation and asystole.[9,10] This report describes a patient with ischemic heart disease whose drug-refractory recurrent ventricular tachycardia was repeatedly and consistently converted to normal sinus rhythm by abrupt forceful coughs performed on command.

Case Report

A 64 year old man with hypertension and two previous myocardial infarctions, the most recent one 2 weeks before admission, was transferred for evaluation of postinfarction chest pain associated with ventricular tachyarrhythmias refractory to conventional drug therapy. Physical examination revealed a blood pressure of 100/60 mm Hg, a regular pulse of 160/min and an apical impulse displaced 2 cm lateral to the mid clavicular line in the fifth left intercostal space. No murmurs or rales were present. The electrocardiogram on admission (Fig. 1, top) revealed ventricular tachycardia. During normal sinus rhythm (Fig. 1, bottom) the QRS axis was −60° and there were signs of an old anteroseptal infarction with slight S-T elevation in leads V_1 to V_4. The chest radiograph revealed cardiomegaly and minimal pulmonary congestion. Twenty-four hour continuous electrocardiographic monitoring demonstrated frequent multiform ventricular premature complexes, as well as episodic ventricular tachycardia requiring cardioversion. A thallium-201 myocardial perfusion scan showed biventricular dilatation with a large perfusion defect in the anterior wall, apex and septum. The gated blood pool scan revealed an akinetic distal anterior wall and hypokinesia of the proximal anterior and inferior walls, with an ejection fraction of less than 30 percent. A His bundle electrocardiogram confirmed the ventricular origin of these tachyarrhythmias (Fig. 2).

Antiarrhythmic therapy and cough induced conversion: Despite therapy with multiple antiarrhythmic agents, including propranolol, procainamide, quinidine, lidocaine and aprindine, an investigational agent, the patient continued to have ventricular tachyarrhythmias, requiring chest thump and external electric countershock daily, until he learned to cough forcefully to convert the

FIGURE 2. His bundle electrogram confirming the ventricular origin of this patient's tachyarrhythmia. The ventricular depolarization begins (**dotted vertical line**) before the His bundle deflection (H) and independently of the atrial deflection (A). HBE = His bundle electrogram; RA = right atrial electrogram.

ventricular tachycardia. By performing repeated forceful coughs on command, the patient himself successfully converted 33 episodes of ventricular tachycardia (Fig. 3). The episodes were usually associated with a decrease in blood pressure and averaged 25 seconds in duration (range 3 to 34 seconds). A single cough was seldom successful in converting the tachycardia; several coughs in close succession were usually required. Both chest thump and external electric countershock were required daily except on the days when the patient was able to cough (Table I). After the patient became disoriented because of poor cerebral perfusion (secondary to left ventricular dysfunction) and possible effects of drug therapy, he was no longer able to cough as directed, and external electric counter-shock again became necessary daily until he died.

Discussion

The episodes of cough-converted ventricular tachycardia in this patient demonstrate the usefulness of the cough in abolishing potentially fatal ventricular tachyarrhythmias. Although spontaneous conversion of ventricular tachycardia may have also occurred in this patient, both chest thump and external countershock were still required daily whenever patient was unable to cough as directed, yet neither was needed when coughing was possible. The cough-induced conversion may have been facilitated by drug therapy. However, because coughing successfully converted ventricular arrhythmias with both the narrow (Fig. 1 and 2) and the wider (Fig. 3) ventricular complexes, it appears unlikely that the drug-related QRS widening was solely responsible for the arrhythmia conversion.

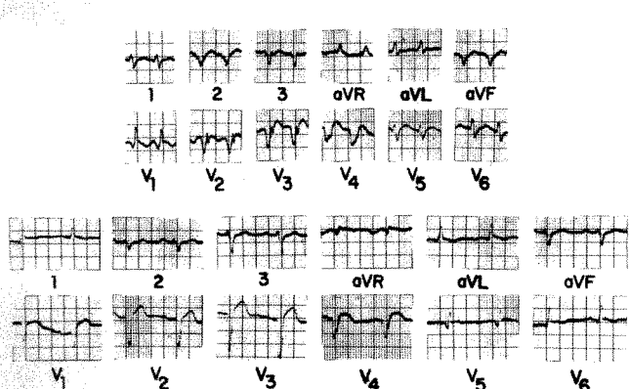

FIGURE 1. Electrocardiograms obtained (**top**) during ventricular tachycardia confirmed by His bundle electrograms and (**bottom**) later the same day during normal sinus rhythm.

Mechanisms of cough conversion of ventricular tachycardia. Although it is not clear how the cough converts ventricular tachycardia to normal sinus rhythm, several mechanisms may be considered. One possibility is the conversion of mechanical input into electric activation resulting in depolarization, the mechanism proposed to be responsible for conversion induced by chest thump.[11,12] Another possibility is that increased coronary perfusion decreased myocardial ischemia. Increased perfusion could result from the increase in aortic pressure as well as reflex coronary vasodilatation caused by activation of baroreceptors and pulmonary inflation reflexes.[3,13,14] However, decreased left ventricular filling as a result of the cough may cause changes in conduction and automaticity.[15–17] In addition, although vagal innervation of the ventricles is sparse,[18,19] vagal stimulation could alter the electric properties of ventricular tissue.[20] It is likely that a combination of factors may be responsible for cough-induced conversion of ventricular tachycardia to sinus rhythm.

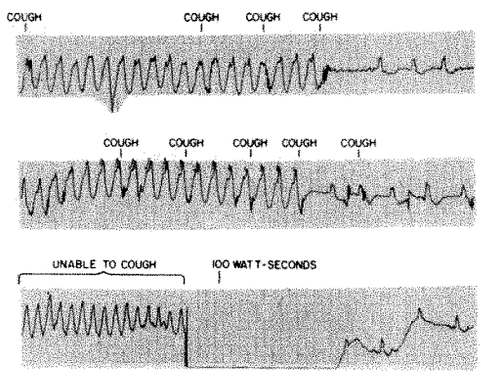

FIGURE 3. Three tracings taken during ventricular tachycardia. The **two top tracings** demonstrate conversion to normal sinus rhythm by repeated coughs, as marked by the **vertical lines.** The **bottom tracing,** taken after the patient was unable to cough as directed, shows that external countershock (100 WATT SECONDS) was required for conversion. The rate of tachycardia in the three tracings was altered as a result of drug therapy. A single cough was seldom successful; several coughs in close succession were usually required.

Mechanical and electric energy produced by cough: In external direct current countershock, as little as 1 to 10 joules may be required to convert ventricular tachycardia to normal sinus rhythm.[9] For external chest thump, the threshold for ventricular depolarization ranges from 0.04 to 1.5 joules.[21] With intraventricular electric stimulation, the energy required ranges from about 0.00003 to 0.0002 joules. With intrathoracic stimulation (that is, during a cough), the amount of energy required for conversion is not known. However, the energy from chest thump may be dissipated over a portion of the chest; therefore, the energy requirement of the cough might be similar to that of the chest thump.

During a cough the intrathoracic pressure usually increases by 50 to 250 mm Hg, and may increase by as much as 450 mm Hg.[15] The linear air velocity is 50 to 120 m/s, and may go as high as 280 m/s, approaching the speed of sound.[22,23] The amount of air expired during a cough normally ranges from 1 to 3 liters.[24,25] From these values, one would estimate the amount of kinetic energy generated to be about 1 to 25 joules. Thus, strictly on the basis of energy considerations, it may be feasible for the cough to produce sufficient mechanical energy to cause cardiac depolarization.

Advantages of the cough in converting ventricular tachycardia: In comparison with other methods of arrhythmia conversion, coughing is simple and easy to perform with minimal instructions, and it may be done even when the patient's position or location is not easily accessible to personnel. There is no trauma or complication, such as burns, chest fractures or myocardial injury. Because it requires no additional personnel or equipment, this method is readily available. In contrast to the use of electric countershock, in which time is needed to obtain the defibrillator, apply the electrode jelly, charge the equipment fully and position the electrodes on the chest, no delay is necessary for the cough. Also, in contrast to drug therapy, in which a time lag exists between intervention and the onset of effect, no critical time is lost, because the cough can be immediately performed and is immediately effective. Furthermore, the cough can enable a patient to maintain consciousness even when the ventricular arrhythmia persists.[3]

Although cough-induced arrhythmia conversion appears to be a relatively rare phenomenon, its significance remains undetermined. Coughing was successful in two other patients with ventricular tachycardia that occurred after injection of intracoronary contrast medium in the cardiac catheterization laboratory. However, because in each case the arrhythmia was a single episode and there was no recurrence, it is possible that the tachycardia might have reverted spontaneously after withdrawal of the catheter and dissipation of the contrast medium.

Clinical application: During the initial moments of ventricular tachycardia, when personnel and equipment are not immediately available, the defibrillator is being charged, the patient is still conscious, the myocardium is not markedly ischemic and the energy requirement for cardioversion is still low, the patient should be instructed to cough forcefully and repeatedly. The electrocardiogram should then be checked for any changes in rhythm before chest thump or electric countershock is administered.

PROBLEM:

ECG STRESS TEST RESULTS

CHEST PAIN	NORMAL	EQUIVOCAL	ABNORMAL
ABSENT	NORMAL	?	?
ATYPICAL	?	?	?
ANGINA	?	?	ABNORMAL

It is now generally accepted that ECG Stress Testing, alone, is insufficiently sensitive and insufficiently specific to be diagnostic in many cases. (Ref. 1-8)

ANSWER: CKG™* (CARDIOKYMOGRAPHY)

Recent investigations have shown that a second test such as CKG,™ Thallium Scintigraphy or Fluoroscopy can substantially increase diagnostic accuracy. (Ref. 2)

WHY CKG™?

The CKG™ provides an accurate, easy to interpret analog representation of left ventricular wall motion. (Ref. 9)

CKG™ is a non-invasive low cost test that can be done in the office right along with ECG Stress Testing.

You probably want to know a lot more about this important new technique. Call or write for additional information.

Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief Heart Institute, Chaim Sheba Medical Center, Tel-Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon — indeed, *every physician* — should have a good basic knowledge of The Pre-Excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is broght a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

NITROSTAT®
(nitroglycerin tablets, USP)

INDICATIONS
Nitrostat is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally, particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

0.15 mg (1/400 grain): N 0071-0568-24 [06]—Ctn. of 10 bottles of 100 tablets; N 0071-0568-13—Convenience Package.

0.3 mg (1/200 grain): N 0071-0569-24 [06]—Ctn. of 10 bottles of 100 tablets; N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain): N 0071-0570-24 [06]—Ctn. of 10 bottles of 100 tablets; N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain): N 0071-0571-24 [06]—Ctn. of 10 bottles of 100 tablets; N 0071-0571-13—Convenience Package. **YF**

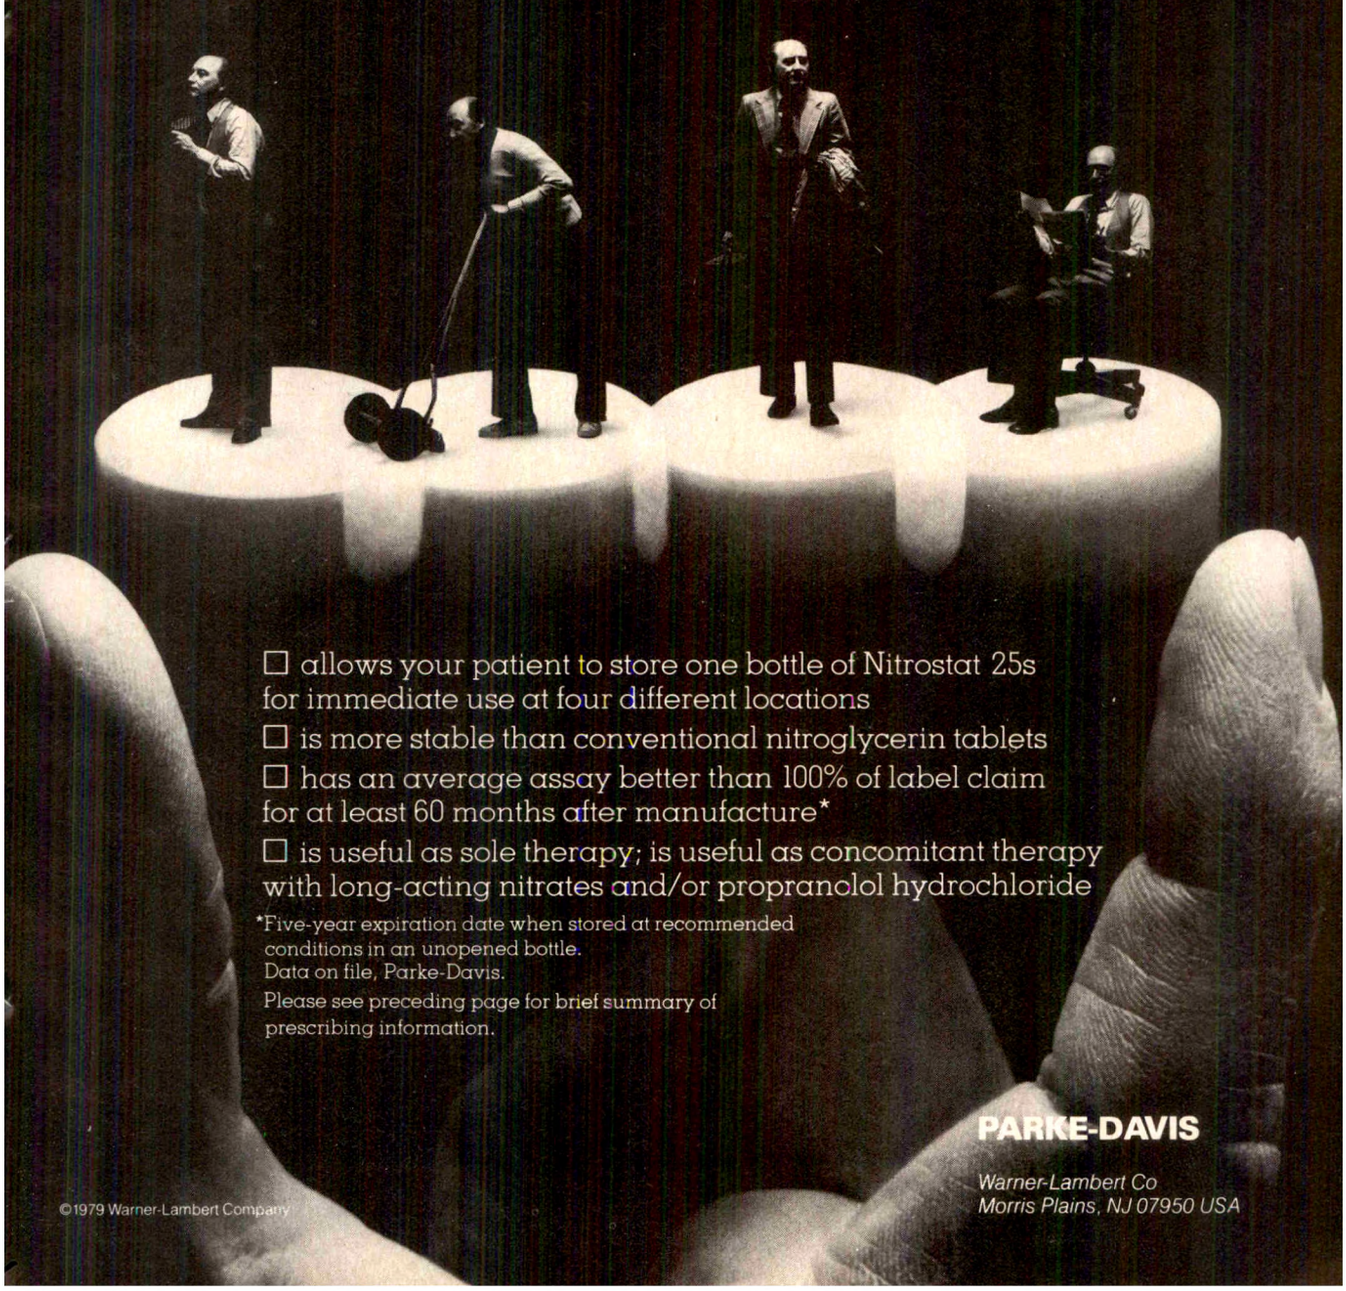
PD-JA-2810-1-P (7-79)

At the critical times of an angina attack...

NITROSTAT®

(nitroglycerin tablets, USP)

4x25s



☐ allows your patient to store one bottle of Nitrostat 25s for immediate use at four different locations

☐ is more stable than conventional nitroglycerin tablets

☐ has an average assay better than 100% of label claim for at least 60 months after manufacture*

☐ is useful as sole therapy; is useful as concomitant therapy with long-acting nitrates and/or propranolol hydrochloride

*Five-year expiration date when stored at recommended conditions in an unopened bottle.
Data on file, Parke-Davis.

Please see preceding page for brief summary of prescribing information.

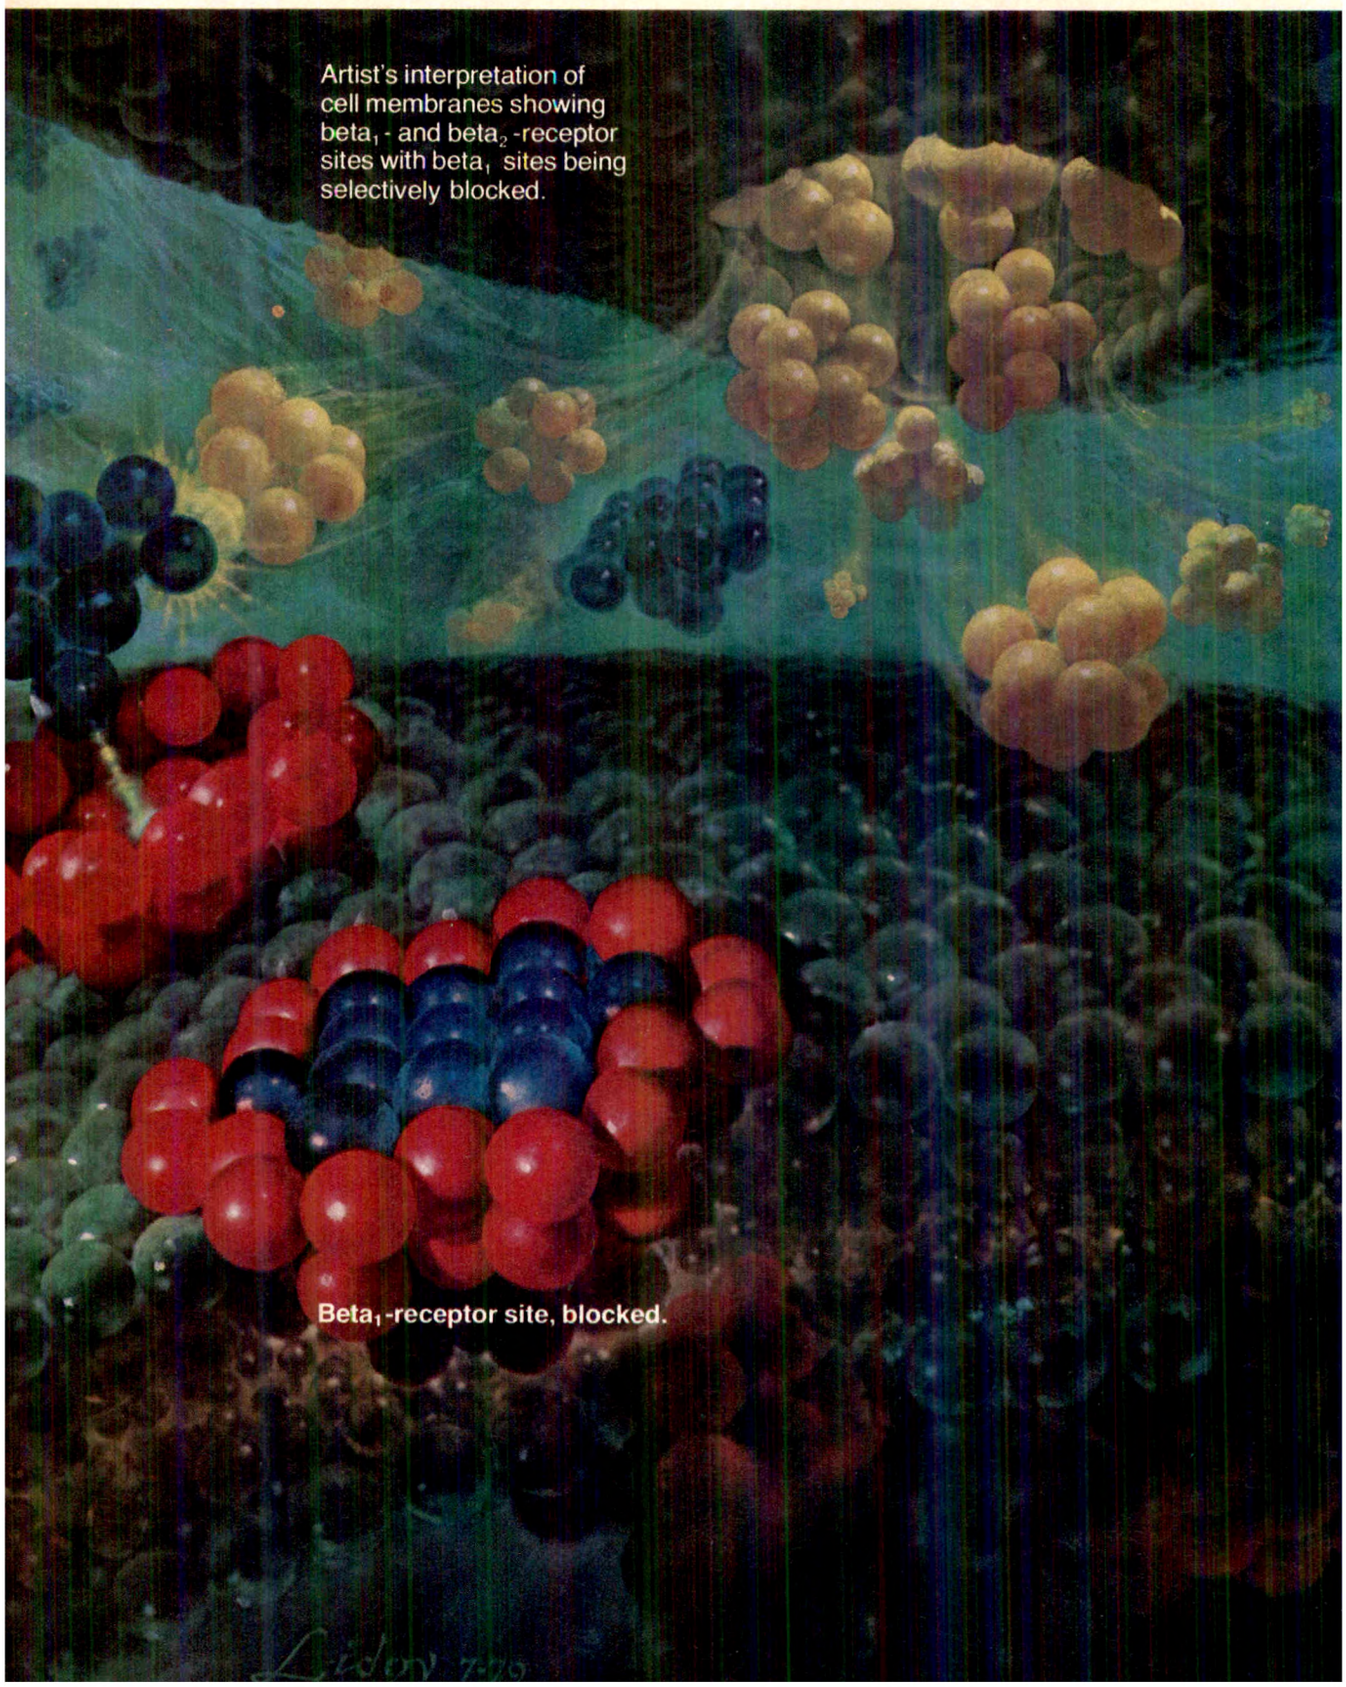
the preferential effect

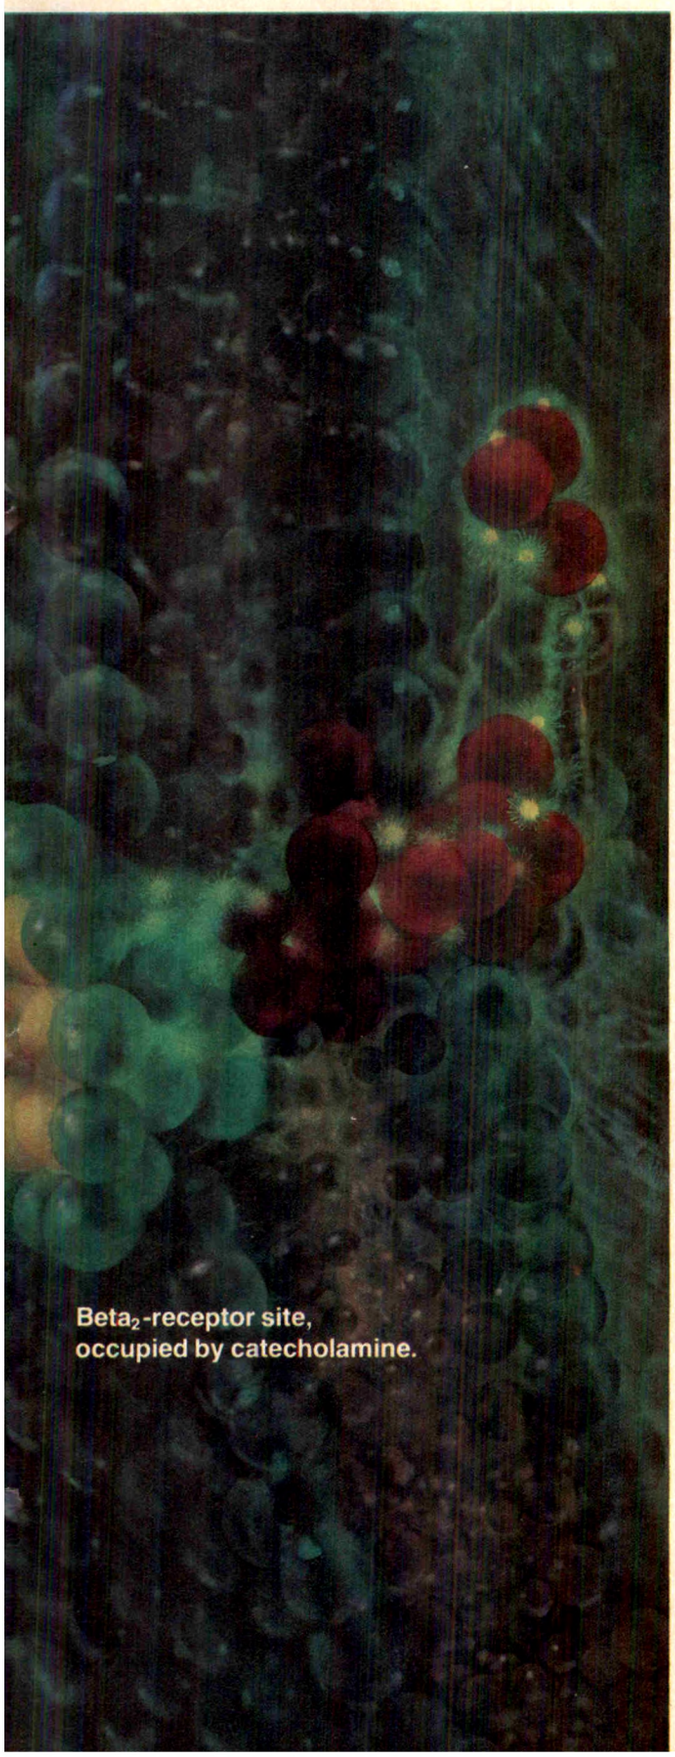


Artist's interpretation of cell membranes showing $beta_1$- and $beta_2$-receptor sites with $beta_1$ sites being selectively blocked.

$Beta_1$-receptor site, blocked.

Lopressor
metoprolol tartrate

works where it should– not where it shouldn't in hypertension



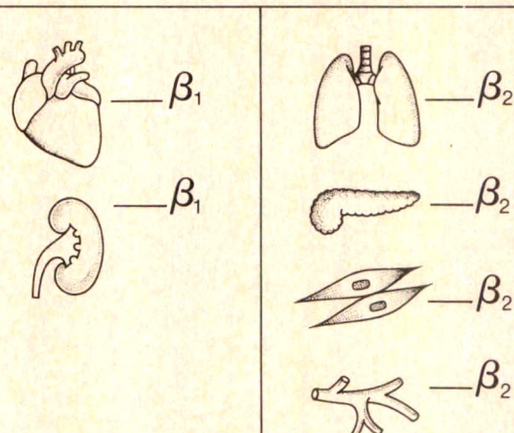
Beta$_2$-receptor site, occupied by catecholamine.

The beta blocker with a significant preference for beta$_1$ receptors in the heart*

Lopressor represents a major step forward in more specific beta blockade.

Unlike the nonselective beta blocker, propranolol, which indiscriminately blocks both beta$_1$ and beta$_2$ adrenoreceptors, Lopressor is relatively selective, that is, it exerts a preferential effect on beta$_1$ receptors in the heart—those involved in lowering blood pressure. Lopressor, at usual therapeutic doses, has a much lower affinity for beta$_2$ receptors.

Beta$_1$-and beta$_2$-receptor sites



Works where it should... not where it shouldn't.

*Hansson L, Werkö L: Beta-adrenergic blockade in hypertension. Am Heart J 93(3):394-402 (Mar.) 1977.

Please see next page for brief prescribing information.

Geigy

Lopressor®
metoprolol tartrate

works where it should... not where it shouldn't

Very well tolerated

- unlike traditional sympathetic inhibitors, there is usually no sed tion, sexual dysfunction or postural hypotension with Lopressor
- most side effects mild and transient

The most frequently reported adverse reactions (which occurre in approximately ten out of 100 patients) are tiredness and dizz ness. Depression and diarrhea have occurred in about five out 100. Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt c diac failure.

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety adverse effects not listed above have been reported with other beta-adrenergic blocking agen and should be considered potential adverse effe of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time a place, short-term memory loss, emotional lability slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with achiing and sore throat, laryngospasm and respir tory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blooc urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopress should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added t diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum e fect of any given dosage level will be apparent af one week of therapy. Usual maintenance dosage approximately 100 mg twice a day, with a range c 100 to 450 mg per day. Dosages above 450 mg p day have not been studied. While twice-daily dos ng is effective and can maintain a reduction in blood pressure throughout the day, some patient especially when lower dosages are used, will exp rience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughc the day. If control is not adequate, a larger dose, three times daily therapy, may achieve better con trol. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room ter perature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shape scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Printec in U.S.A. 667292 (8/79) C79-22

The potassium
masquerade
is over

Potassium with nothing to hide

There's no longer any need to try to hide the taste of potassium chloride—because KAON-CL TABS have no taste.
Thus your patients who can't or won't take liquid supplements have an acceptable alternative that enables them to get the potassium they need.

Wax-matrix tablets minimize likelihood of GI complications.
The special wax matrix used in KAON-CL TABS permits gradual release of potassium chloride in the GI tract. Because the potassium is slowly released, the possibility of high localized GI concentrations is limited. The reported frequency of GI lesions with wax-matrix tablets is less than one per 100,000 patient-years. There have been only two equivocal cases of GI bleeding reported with KAON-CL TABS to date and no reports of small bowel stenosis or ulceration. However, clinical experience is insufficient at this time to indicate that the incidence is other than the stated numerical ratio.

Logical, easily adjustable dosage. One tablet t.i.d. provides 20 mEq of potassium, the amount generally considered necessary for prevention of hypokalemia. Two tablets t.i.d. provide 40 mEq of potassium, usually adequate for the treatment of mild potassium depletion. Dosage should be adjusted to individual patient needs. In cases of more severe potassium depletion, 100 mEq daily or more may be required.

Patients stay on

KAON-CL TABS®
(potassium chloride) Controlled Release Tablets

BRIEF SUMMARY
KAON-Cl TABS® (potassium chloride) Controlled Release Tablets

Description: Kaon-Cl Tabs is a sugar coated (not enteric-coated) tablet containing 500 mg potassium chloride (equivalent to 6.7 mEq potassium chloride) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

Indications: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUIDS OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For the prevention of potassium depletion when the dietary intake is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure, hepatic cirrhosis with ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, and with certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene)

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium. Potassium supplementation, when indicated in such patients, should be with a liquid preparation.

All solid dosage forms of potassium chloride supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

Warnings: *Hyperkalemia*—In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics—Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions—Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Kaon-Cl Tabs (potassium chloride) is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient years. Kaon-Cl Tabs should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention or gastrointestinal bleeding occurs.

Metabolic Acidosis—Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

The most severe adverse effects are hyperkalemia (see Contraindications, Warnings and Overdosage) and gastrointestinal obstruction, bleeding or perforation (see Warnings).

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following:

1. Elimination of foods and medications containing potassium and potassium-sparing diuretics.
2. Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10-20 units of crystalline insulin per 1,000 ml.
3. Correction of acidosis, if present, with intravenous sodium bicarbonate.
4. Use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

Caution: Federal law prohibits dispensing without prescription.

How Supplied: Bottles of 100, 250 and 1000.

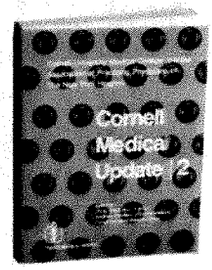
Now in book form...the latest Update Your Medicine lectures.

CORNELL MEDICAL UPDATE/2



Edited by LILA A. WALLIS, MD, FACP

Helps you keep up with the new advances in your specialty in the comfort of your home or office.

Just published with all new material—specialties expanded.

The series CORNELL MEDICAL UPDATE breaks all medical book tradition with its workbook format that gives practicing physicians a quick overview of the latest advances in their speciality. It transcribes into book form the Update Your Medicine lectures sponsored by New York Hospital-Cornell Medical. These lectures are well-known for helping physicians prepare for Recertification despite the demands of a heavy practice.

The new approach of the first volume was so well-received that it went through three printings in less than two years. Now the just published CORNELL MEDICAL UPDATE/2 takes up where the first volume left off. It has been specially designed for the practicing physician who has difficulty keeping up with the growing literature of the field. Each chapter transcribes one of the lectures and covers a specific speciality in-depth from basic physiologic and chemical principles to its clinical applications.

Lila A. Wallis, MD, FACP, the series editor, has eliminated all the filler material a *continuing* education does not need. You won't find historical reviews or a rehash of material you've known since medical school. You will find the practical, life-saving knowledge a dynamic practice depends on. Because the lectures have been edited for easy reading and laid out for quick comprehension, you'll be able to incorporate all the material into your own professional technique.

Earn 25 Credits Towards AMA Physician's Recognition Award. CORNELL MEDICAL UPDATE/2 has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit are included with every copy.

Yorke Medical Books, 666 5th Ave., P.O. Box 876, N.Y., N.Y. 10019

Please send me a copy of CORNELL MEDICAL UPDATE/2 at $38.00. I may use the book for 30 days and if not completely satisfied, return it for full credit or refund.

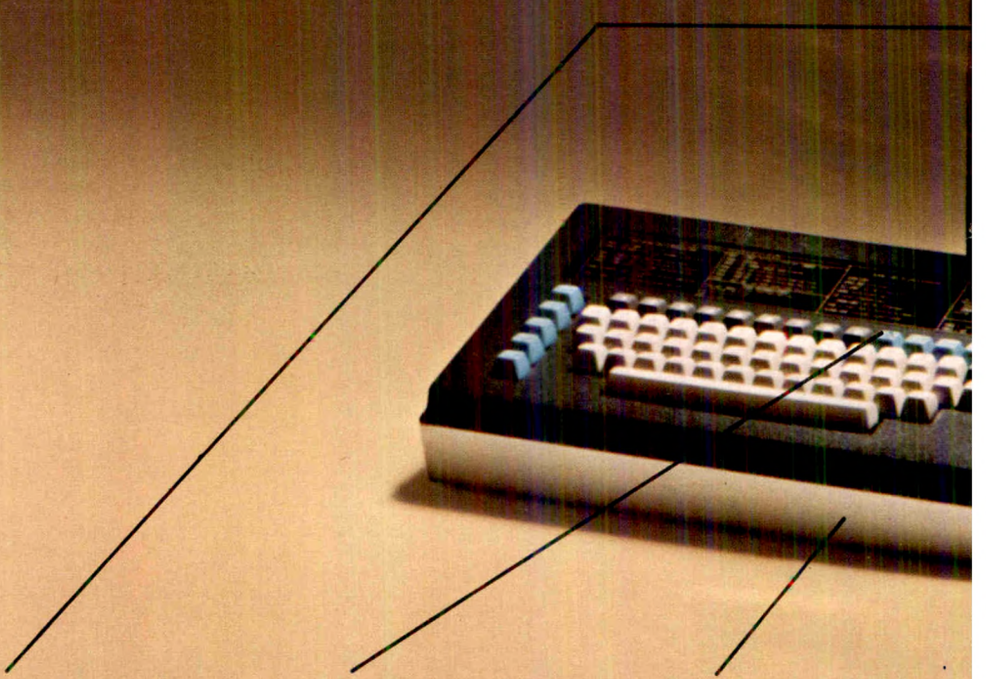
VALID REASONS
WHY YOU SHOULD
HAVE M.A.D. COLOR
VIDEO DATA SYSTEMS
FOR YOUR I.C.U.-C.C.U.
NURSE'S STATION
MIDWEST ANALOG & DIGITAL
MIDWEST
ANALOG
& DIGITAL
INC.
Howard Young Medical Center 16 Bed I.C.U.-C.C.U., Woodruff, Wisconsin
(Shown are 2 of the four screen M.A.D. Nurse's Station)

HERE'S PROOF THAT M.A.D. DELIVERS MORE FOR LESS THAN ANY OTHER SYSTEM!



Never Obsolete! The originally installed equipment always remains the same. Only the program need be inexpensively changed if you want to update your present capabilities.

Connects with any bedside equipment you already have or wish to change to in the future. Connects with little or no modification of either our system or your bedside equipment.

Works independently of readouts and alarms of bedside equipment to give you a double check of accuracy.

Cursor feature provides opportunity for waveform examination: time intervals within ECG's and pressure traces; specific values of pressures or trends; mean, maximum and minimum values of pressures within selected intervals.

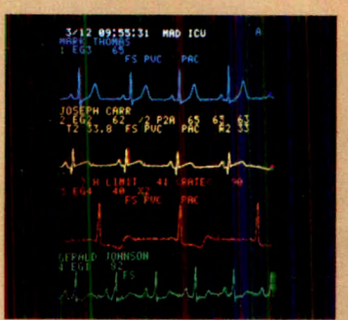
Color coded, non-fade patient trace, numbers, and text all shown on the same screen.

Displays ECG's, multiple blood pressures, temperatures, respiration, cardiac output, arrhythmia rate and trend, for each patient, coded in color, all on the same screen.

Special automatic arrhythmia recording is assignable to any and all patients.

Alarm interrupts both manual and automatic recording. Equipment resumes original recording after alarm.

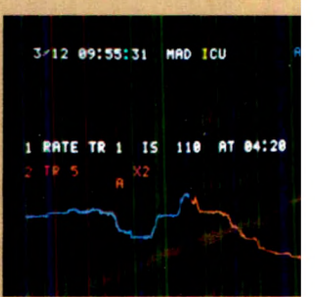
High *and* low alarm thresholds digitally set for *all* parameters.



Shows *both* alarms and near alarms in different special colors independent of bedside equipment.

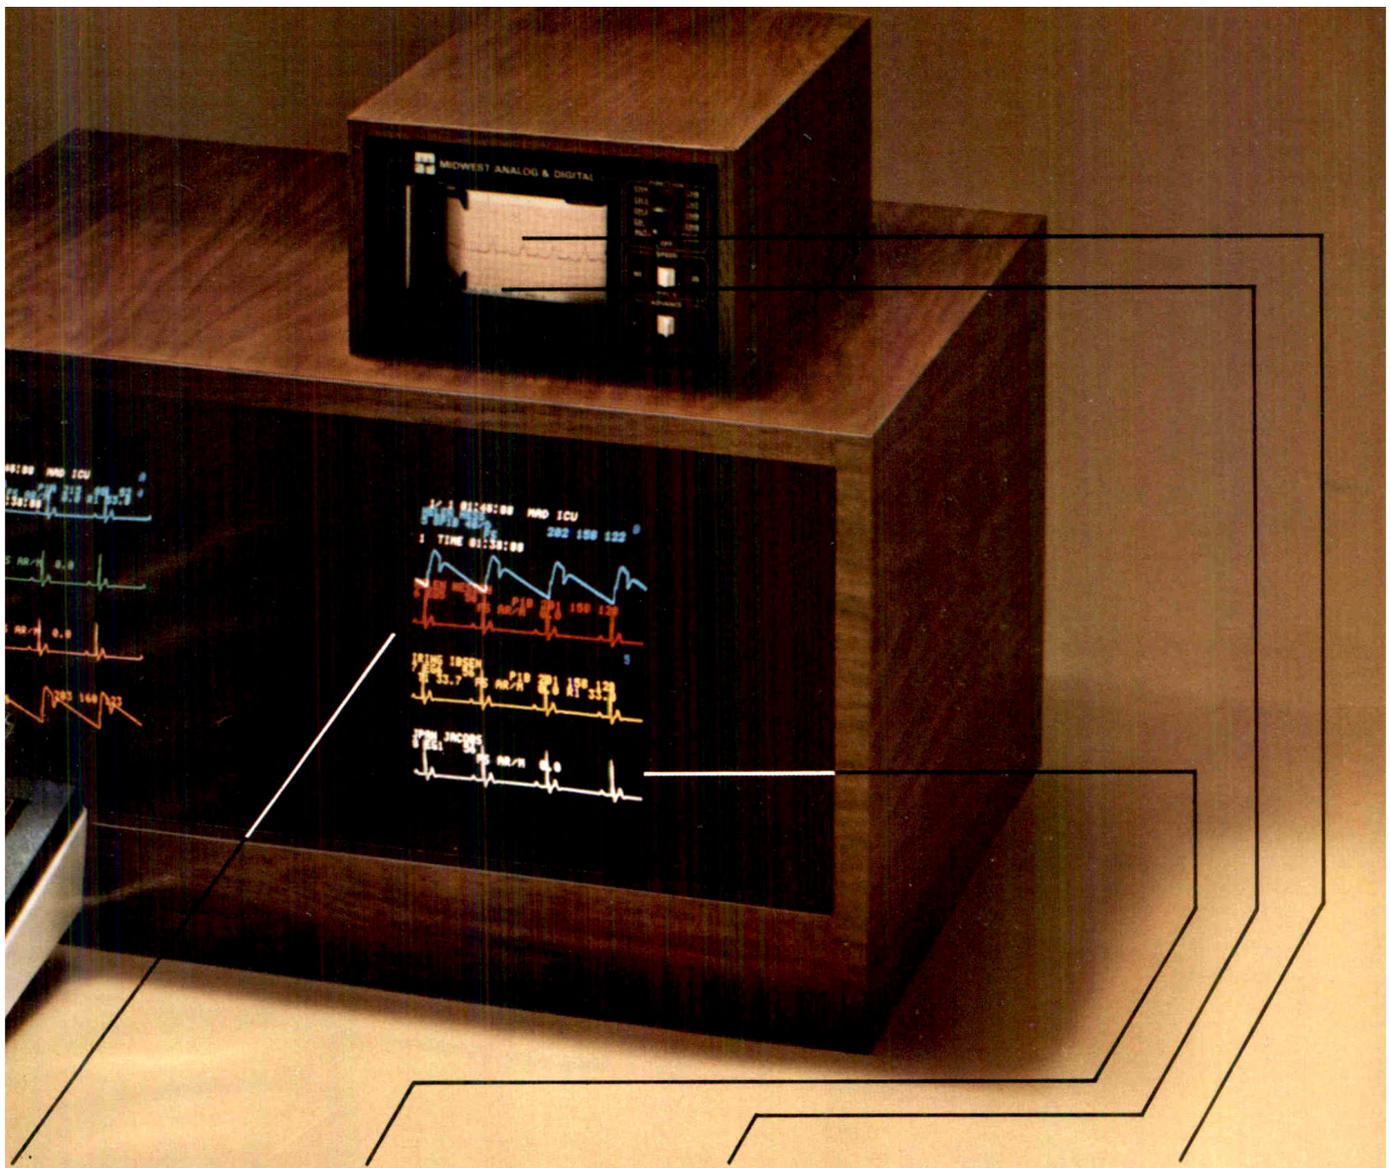
Alarm gives you special alarm colors, flashing readout, audible alarm and automatic chart recording. Standby mode does not shut off alarm color change.

Easy to use keyboard. Loc like a typewriter. Works li a hand calculator. Worki knowledge can be gained 15 minutes.

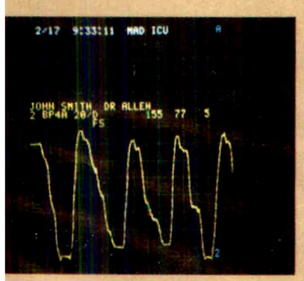


Trending, both short and lo term is fully automatic a versatile. Done on all para eters, analyzed with dig precision and hard copie

The screen shows you eve thing! You can get accura readings of the Systolic, astolic and Mean pressu from a screen for any and patients all the time.



to 8 parameters and 8 ital readouts per channel y be assigned to any pa- nt. Can examine up to 64 rameters and readouts on typical two screen (8 pa- nt) system.



curate grid may be dis- yed behind traces for visu- onfirmation of calibrations.

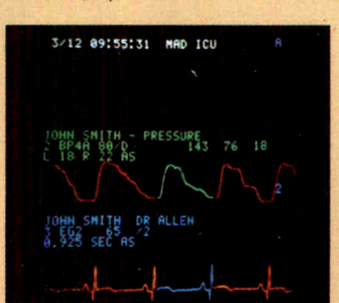
ces can be enlarged or re- ced or positioned any- ere on the screen. Calibra- n and baseline identifi- ion are never lost even ugh traces are manipu- ed.

Clean, simple display. Only the required data need be displayed.

Any trace, including pressures, can be cascaded to any other available screen space. Color coding is automatic.

The M.A.D. system is a preprogrammed computer system customized to fit your needs. It is lower in price than non-computerized systems of far less capability that are limited in their ability to be updated without adding more modules.

Automatically prints patient's name, doctor's name, time and date onto chart recording. All parameter values for that patient are also printed. Annotates every ten seconds with up-to-date printed readouts while recorder is running . . . all independent of bedside equipment.



Calculations and analysis may be done on any portion of a frozen waveshape by cursors (color, pointers or vertical lines). ECG's and pressures may be frozen together for comparison.

ECG, pressure, or other waveforms, even trends can be strip recorded manually or automatically.

Since the M.A.D. system is computerized and not hardwired, the nurse can assign any of these features to any bed, collect patient data from remote locations, interconnect to other nurse's stations . . . this allows maximum use of the system at all times. Eliminates the need for additional modules and additional staff.

You don't buy anything you don't need or will use only infrequently. Everything you purchase is put to practical use.

Only M.A.D. gives you all this capability in a four square foot area.

MIDWEST ANALOG & DIGITAL INC.

JUST ANOTHER MONITORING SYSTEM?

NOT WITH M.A.D.

Midwest Analog & Digital, Inc. was created by doctors and engineers to present patient monitoring systems that, for the first time, give you everything you require at an affordable price. A system that never becomes obsolete . . . that will never require a hardware change . . . that can be updated at anytime . . . that provides functions you could only wish for before . . . that puts the nurse back at the bedside . . . that allows doctors research capability without additional expense . . . that assures biomedical engineers of minimum maintenance.

Installations are available across the country for your viewing or we will provide demonstrations in your area at your request. M.A.D. has the only monitoring system that can be customized to meet your exact needs without additional modules or extra cost.

Around-the-clock service as near as your telephone.

Just call your local area M.A.D. representative. M.A.D. provides factory trained service representatives at any time of the day or night.

5 YEAR WARRANTY

An industry first! The advanced technology, rigid quality controls and five year in-use field testing of the M.A.D. ICU/CCU System in Hospitals throughout the country allow us to give you the most comprehensive Warranty in the market. This also assures you of the superior quality of the M.A.D. Color Video Data System*

*See us or your M.A.D. Representative for complete Warranty details.

We don't stop at coronary care and intensive care.

Hypertrophic Cardiomyopathy: A Disease in Search of Its Own Identity*

JOHN F. GOODWIN, MD, FACC

London, England

The search for the identity of hypertrophic cardiomyopathy continues. The paper by Yamaguchi et al.[1] in a recent issue of this Journal draws attention to another variation in the spectrum. These workers describe 30 patients in a series of 1,002 consecutive patients investigated with left ventricular angiography and coronary arteriography whose electrocardiograms showed giant inverted T waves with high QRS voltage in the absence of systemic hypertension or occlusive coronary artery disease. In all 30 patients the ventriculogram in the right anterior oblique projection revealed a characteristic spade-like configuration due to concentric apical hypertrophy of the left ventricle and associated with obliteration or elimination of the cavity of the apical portion of the left ventricle at end-systole. Two dimensional echocardiography revealed a similar configuration. No systolic pressure gradient was found even on provocation. The upper half of the septum remained thin instead of bulging into the left ventricle, and systolic anterior motion of the mitral valve was not seen. Many of the cases with apical hypertrophy did not have asymmetric hypertrophy of the septum.

The angiographic appearance was contrasted with the "banana" shape observed in hypertrophic obstructive cardiomyopathy in which the authors claim the free wall thickness is increased in all segments. It was not associated with obliteration of the cavity at the apex and the septum was rhomboid in shape in systole in the left anterior oblique projection. All patients showed electrocardiographic abnormalities between the 2nd and 6th decade of life. In four patients, there was a striking progression of electrocardiographic changes over a period of only a few years.

From the Royal Postgraduate Medical School, Hammersmith Hospital, London, England.

Address for reprints: John F. Goodwin, MD, FACC, Royal Postgraduate Medical School, Hammersmith Hospital, Ducane Road, London W12 OHS, England.

The conclusions presented in this important paper prompt a further look at the terminology and status of hypertrophic obstructive cardiomyopathy and indicate the need for a voyage of appraisal around its shores. The more that is written about hypertrophic obstructive cardiomyopathy/idiopathic hypertrophic subaortic stenosis (HOCM/IHSS) the more confused the disease tends to become and the more its identity is threatened. As more data accrue and further dogma is stripped away, the image blurs and a different picture, not always clearer than that before it, emerges. Finally, the disease threatens to disappear entirely into other cardiac disorders leaving behind merely the mocking smile of the Cheshire cat. Is hypertrophic obstructive cardiomyopathy one disease, many diseases or no disease at all, but merely a collection of abnormalities put randomly together as a result of the effects on the heart of various other cardiovascular disorders such as hypertension and valvular and congenital heart disease? It would be a disaster if the important condition of hypertrophic cardiomyopathy were to disappear in this way. However, Bulkley[2] has warned against the troublesome "Idols of the cave and marketplace" and has advised caution in applying unified concepts too readily. In my view the time has come to take stock and to question whether research workers in this field may be confusing and overcomplicating the issue and in so doing ignoring the clues obligingly left behind by nature for us to pick up.

Diagnostic Problems

A major problem is the difficulty of finding a firm diagnostic base in many cases. While the typical patient with hypertrophic obstructive cardiomyopathy usually presents no difficulty in diagnoses at the bedside and has characteristic physical signs, angiographic findings and echocardiographic evidence of massive septal hypertrophy and other features, the diagnosis in patients

* Editorials published by the Journal reflect the views of the authors and do not necessarily represent the views of the Journal or the American College of Cardiology.

without "obstruction" may cause great difficulty even with all the diagnostic aids including biopsy and microscopic examinations. Semantic problems abound; frequently terms are used synonymously but without justification; is hypertrophic obstructive cardiomyopathy really the same as idiopathic hypertrophic subaortic stenosis? Strictly speaking, no, for the latter refers only to the "obstructive" element of the cardiomyopathy. "Hypertrophic cardiomyopathy" is a useful diagnostic label and fortunately has specificity because of the basic definition of cardiomyopathy as a "disorder of heart muscle *of unknown cause*."[3] If this definition is applied, then other causes of hypertrophy of the left ventricle such as hypertension and aortic valve disease should automatically be excluded. The same argument would apply to the right ventricle in cases of pulmonary stenosis, for example. Therefore the term "hypertrophic cardiomyopathy with or without obstruction" is a useful starting point. Providing we understand this, the term hypertrophic obstructive cardiomyopathy and its abbreviation HOCM may still be used.

It would have been very convenient if the myofibrillar disarray[4] in hypertrophic obstructive cardiomyopathy had not been found in cases with other causes of ventricular hypertrophy such as pulmonary stenosis and aortic stenosis. This finding of disarray in other forms of cardiac disease has caused dismay and bewilderment and has led to a weakening of the concept of hypertrophic obstructive cardiomyopathy as a single disease and to the suggestion that it may merely be the result of other diseases acting on the myocardium. However, although small areas of myofibrillar disarray may be seen in many conditions, widespread disarray is virtually diagnostic.[5] But the full extent of the lesions cannot now be diagnosed in life.

Role of Intraventricular Obstruction

Confusion has also arisen as a result of undue emphasis on the role of obstruction, based on the presence of a resting or provokable systolic pressure gradient within the left ventricle. It has been assumed that a pressure gradient necessarily means obstruction but this is not so, as shown by Criley and his colleagues.[6] The concept of impairment of diastolic function as the most important feature of the disease and of "obstruction" as merely an incidental feature has not received as much attention as it should. Swan et al.[7] noted that disappearance of obstruction was usually a sign of increasing severity of the disease, and Maron et al.[8] showed that when the malorientated fibers were widely distributed in the apex or posterior wall of the left ventricle obstruction was absent, whereas the myofibrillar disarray was confined to the septum in patients who had obstruction. The knowledge that disappearance of signs of obstruction usually indicates increasing spread of the disease and the evidence that obstruction may be absent both in mild and in very severe disease should emphasize the view that obstruction is peripheral to the central problem of myocardial function in hypertrophic obstructive cardiomyopathy, which is mainly a fault of relaxation and ventricular filling.[9,10]

Definitive Diagnostic Criteria

The search for a "gold standard" for diagnosis continues. The demonstration of myofibrillar disarray in a small fragment of septum obtained by endomyocardial biopsy clearly cannot be used, although if the circular arrangement of short thickened fibers seen on light microscopy is found in association with myofibrillar disarray on ultrastructural study, the probability of hypertrophic obstructive cardiomyopathy is high. Many of the echocardiographic criteria have been shown to be nonspecific, especially systolic anterior movement of the mitral valve and disproportionate asymmetric hypertrophy of the ventricular septum. The electrocardiogram may be virtually diagnostic when all features of atrial and ventricular hypertrophy, septal Q waves, deep T wave inversion and short P-R interval are present, but frequently they are not and the electrocardiogram is sometimes normal. Clinical signs may also be misleading. When the three cardinal signs are present—systolic ejection murmur of late onset at the left sternal edge of the apex, jerky arterial pulse and palpable left atrial impulse—the diagnosis is virtually certain. But when these signs are not all present diagnosis becomes much more difficult, especially because there may be no abnormal signs and because hypertrophic obstructive cardiomyopathy can mimic so many other heart diseases, such as "idiopathic" pulmonary hypertension, subvalvular rheumatic or nonrheumatic mitral regurgitation, aortic stenosis, hypertensive heart disease and coronary artery disease.

In cases without conclusive signs more definitive diagnostic criteria are needed. The angiogram provides these criteria in many but not all cases. The characteristic angulated diastolic shape of the left ventricle resembling a banana, the massive hypertrophy of the free wall and septum, the large papillary muscles, elimination of the left ventricular cavity at the end of systole, and the star-like projections of contrast medium into the interstices of the columnae carnae are all characteristic and diagnostic features, but there are variations of this pattern that are not always easy to define. For example, cavity "obliteration" (better termed "elimination" to avoid confusion with restrictive/obliterative cardiomyopathy) is not necessarily due to hypertrophic obstructive cardiomyopathy and may occur in other conditions such as systemic hypertension and aortic stenosis as a response to pressure overload.[11] A typical "hourglass" constriction in the middle of the left ventricular cavity, together with precise localization of a pressure gradient to the mid ventricular area, has been described in hypertrophic obstructive cardiomyopathy by Falicov and Resnekov.[12]

My colleagues[13] have recently analyzed the angiographic patterns of the left ventricle in both "obstructive" and "nonobstructive" forms of hypertrophic cardiomyopathy in 100 patients. Forty-one patients had cavity elimination, 45 had marked mid cavity narrowing, 10 had a normal cavity or slightly prominent papillary muscles and four had a *dilated* left ventricular cavity. Thus in some patients the angiographic ap-

pearance can be confusing. In particular, dilatation of the cavity may lead to confusion with congestive cardiomyopathy. In fact, cavity dilatation is very rare and is probably confined to patients with severe mitral regurgitation (due to secondary mitral valve damage from turbulence, infection or calcification) or to patients with widespread disease leading to heart failure or with transmural myocardial infarction.[14] Clearly the extent and stage of the disease must both be taken into account when one is considering its diagnosis with angiography as well as with other methods. The widely patent smooth coronary arteries are characteristic, but similar appearances also occur in congestive cardiomyopathy, although it has been claimed that narrowing of the septal perforating arteries in systole is characteristic of hypertrophic obstructive cardiomyopathy though not pathognomonic.[15]

Differentiation From Hypertensive Heart Disease

One of the most difficult situations is the differentiation of hypertrophic obstructive cardiomyopathy from hypertensive heart disease. Usually the characteristic angiographic appearances will differentiate the two conditions. Yamaguchi et al.[1] point out that the left ventricle in hypertension shows an oval configuration with an equally thickened free wall, but in certain cases the appearance is not diagnostic of either hypertension or hypertrophic obstructive cardiomyopathy. In such cases the deep T wave changes described by Yamaguchi in apical hypertrophic cardiomyopathy are of importance in suggesting cardiomyopathy.

The claim that hypertrophic obstructive cardiomyopathy can be distinguished from hypertensive heart disease by echocardiography has also been challenged. In our experience[16] M mode echocardiography did not differentiate hypertensive heart disease from hypertrophic cardiomyopathy without obstruction but, when obstruction was present, mid systolic closure of the aortic valve and systolic anterior motion of the mitral valve served to differentiate the two diseases in all but 6 percent of cases. Gehrke[17] claimed that when B scan techniques were used the bright line produced by bulges in the hypertrophied septum with relative damping of the adjacent myocardium appeared to be due to malalignment of myocardial fibers, possibly allowing differentiation from simple septal hypertrophy. The value of two dimensional echocardiography was recently stressed by Martin et al.,[18] who described studies with a wide angle phased array technique that documented unusual echoes within the thick septal myocardium, possibly related to abnormal myocardial structures.

A Clinical Diagnostic Index

How then can hypertrophic obstructive cardiomyopathy be reliably diagnosed? Only by attention to all diagnosistic criteria can reasonably accuracy be achieved. For example, in differentiating hypertensive heart disease from hypertrophic obstructive cardiomyopathy, both the physical signs and the electrocardiogram must be considered. If these do not suggest cardiomyopathy, then M mode echocardiography will be helpful if there are features suggesting a gradient because systolic anterior motion of the mitral valve and mid systolic closure of the aortic valve will differentiate hypertrophic obstructive cardiomyopathy from hypertensive heart disease in most cases. If no gradient is present the echocardiogram cannot reliably differentiate these two types of heart disease. Because a gradient cannot always be diagnosed clinically with certainty, cardiac catheterization and angiocardiography will be necessary in many cases. The angiogram may show characteristic features of hypertrophic obstructive cardiomyopathy, but if it does not, and if it merely reveals hypertrophy without alterations of shape, then the diagnosis cannot be made with certainty, even if a pressure gradient can be provoked. The diagnostic label then remains uncertain. This uncertainty must be faced and no attempts made to force the case into a diagnostic box for the sake of uniformity.

TABLE I

Probability of Diagnosis

1. *Certain diagnosis*
   - A. Typical clinical signs and history.
     All echocardiographic criteria
   - B. Equivocal clinical signs.
     All echocardiographic criteria.
     All angiographic criteria
   - C. Equivocal physical signs.
     Some echocardiographic criteria.
     All angiographic criteria
2. *Probable diagnosis*
   Equivocal physical signs.
   Some echocardiographic features.
   Suggestive angiographic features
3. *Uncertain: diagnosis not possible*
   Equivocal physical signs.
   Some echocardiographic features.
   Equivocal angiographic features

Experience suggests that there are many cases in which the exact diagnosis cannot readily be made with current techniques of investigation, although two dimensional echocardiography promises well. A rough diagnostic index is suggested in Table I. Naturally the history of the patient and the presence or absence of a family history, particularly of sudden death, must be taken into account in evaluating the clinical aspects.

Is Hypertrophic Cardiomyopathy One Disease?

The existence of severe widespread hypertrophic obstructive cardiomyopathy without any apparent cause for the hypertrophy provides strong evidence that the disease is indeed an entity in its own right. It seems likely that there is a thread of similarity in all patients with features of hypertrophic obstructive cardiomyopathy even though the physical signs may be diverse. This suggests that it is a single disease with protean manifestations. The lack of difference in proved familial and nonfamilial cases suggests that there is a genetic basis in all cases, even though it may not be detectable in many. Because the disease has been described in newborn infants there is reason to suppose that it begins before birth. The similarity between the myocardial structure in the heart with hypertrophic obstructive

cardiomyopathy and in primitive hearts, such as that of the salamander, suggests that the disease may be a disorder of the developing myocardium.[19] I have already drawn attention[20,21] to the clues that suggest that the cause may be a disorder of catecholamine function: mainly, the responses of function to beta adrenergic stimulation and blockade, the association with thyroid hyperfunction,[22,23] the association with disorders of neural crest tissue and the studies suggesting that administration of catecholamines to experimental animals can cause a syndrome very similar to hypertrophic obstructive cardiomyopathy.[24]

If hypertrophic obstructive cardiomyopathy indeed is one disease, many questions remain to be answered: Why is it associated with so many other congenital heart diseases?[25] Why does myofibrillar disarray occur in a wide variety of conditions associated with hypertrophy, although to a lesser degree than in hypertrophic obstructive cardiomyopathy? What is the difference between symmetric and asymmetric hypertrophy? What determines the spread of the disease through the muscle of the heart? Do other cardiac lesions stimulate its development in some way, or act as a "challenge" to a heart already affected by hypertrophic obstructive cardiomyopathy? Yamaguchi and his colleagues[1] suggest that in their patients a change in the hypertrophic process of the myocardium had occurred in middle age, perhaps as a response to arterial hypertension or catecholamines.

The "lumpers" and "splitters" will continue to argue whether hypertrophic obstructive cardiomyopathy is one disease or many, but while the debate proceeds it is important not to lose the thread that binds the multiple variations of this condition together. The clamor of the marketplace should not drown the voices of the true gods within the cave.

AORTIC AND LEFT HEART CHAMBER SIZE IN ATRIAL SEPTAL DEFECT—I

The precise criteria for measurement of structures on M mode echocardiography were not standardized until recommendations were made by the American Society of Echocardiography (ASE).[1,2] In spite of these recommendations, considerable confusion persists, particularly regarding interpretation of the terms "leading" and "trailing edges." This is well illustrated by Figure 1 of the article by DeMaria et al.[3] Although their criteria for measurement of the aortic root and left atrium, as defined in the text, are consistent with the recommendations of ASE, the actual points of measurement in the figure are incorrect. The measurements should have been taken from the points illustrated in the revised illustration (Fig. A). The error introduced by this may be 3 to 5 mm in actual measurements of the aorta and left atrium, respectively, on the particular illustration.

AORTIC AND LEFT HEART CHAMBER SIZE IN ATRIAL SEPTAL DEFECT—II

DeMaria and co-workers showed by their angiographic measurements that left ventricular end-diastolic volume, as well as left atrial size and left ventricular output, are not decreased in patients with atrial septal defect. First, there appears to be some discrepancy in regard to the data. In Table I, their normal value for left ventricular end-diastolic volume index is 62.86 ml/m^2, whereas in the summary and in the results they say that their normal value is 52.9 ml/m^2. The valve of 52.9 for normal end-diastolic volume in older children and adults is one of the smallest I have ever seen. I think this deserves some further explanation in regard to the methodology and diagnoses of the patients. If indeed the normal value was 62.9 and the value in patients with atrial septal defect 50.1, then one wonders if a relook at the statistics might show that the left ventircular end-diastolic volume is indeed smaller. In addition, it would not seem pertinent to include any patients with ostium primum defects in the group with atrial septal defect. These patients may have even small degrees of mitral regurgitation, which may be difficult to quantitate at times and may lead to a larger left ventricle. Finally, the authors should perhaps include only patients in the group with atrial septal defect who had pulmonary to systemic flow ratios of at least 2:1. Some patients had a pulmonary to systemic flow ratio of 1.4:1, a value that suggests one is dealing with a patient with a small atrial defect and one would not expect the left ventricle to be small.

In 1972 our group published data from biplane cineangiocardiograms in 35 patients with large secundum or sinus venosus atrial septal defects.[1] Our data did show that the left ventricle, the ejection fraction and the left ventricular output were slightly smaller than normal. These differences from normal were certainly small and probably of very little hemodynamic significance. However, I expect that data from biplane studies would be more valid in assessing ventricular volumes in this situation than uniplane views using any type of orientation. With the known shape changes I expect only the biplane studies will really be valid.

Finally, I believe that there are occasional patients who have such a very large atrial defect that the left ventricle may be quite small and may be of some hemodynamic significance.

REPLY

I. As a general principle, the American Society of Echocardiography recommended that measurements be performed from the leading edge of all ultrasonic signals. In regard to the aorta and left atrium, the preferred method of measurement was performed in our study, as described in the text of the manuscript and as depicted by the corrected arrows in Figure A.

II. The mean left ventricular end-diastolic volume index for our control subjects was 52.9 ml/m^2, as reported in both the abstract and text of our manuscript; this value is within the normal range for single plane cineangiography in adults and children. Only two patients with an ostium primum defect were included in our study, and neither patient manifested mitral regurgitation on cineangiography. Exclusion of these two patients did not alter the results of our investigation. The vast majority of patients evaluated manifested a left to right intracardiac shunt of 2:1 or greater, and no correlation could be demonstrated between pulmonary to systemic flow ratio and left ventricular volume in our study.

Although data regarding cardiac function in patients with an atrial septal defect have been variable, our findings are certainly consistent with those of Graham indicating that any differences from normal are probably of very little hemodynamic significance except in an occasional patient with a massive defect. We also agree that biplane studies are probably superior to uniplane methods in evaluating left ventricular volume in patients with an atrial septal defect. However, it is unclear why it should be necessary to utilize an angiographic view in which the left ventricle exhibits geometric distortion produced by right ventricular enlargement to demonstrate a reduction in left ventricular size presumably due to generalized underfilling.

EXERCISE TESTING IN CHILDREN WITH HEART DEFECTS

It is indeed encouraging to have one's data confirmed years later and by a different technique. The only obvious problem is that Cumming[1] did not realize that he generally confirmed the prior data. Unfortunately, he combined data from two studies that were markedly different in concept. Our initial report[2] concerned children with moderate to severe disease who were hospitalized for cardiac catheterization or operation, or both, in 1962 and 1963. These were, in many cases, children from the backlog of presurgical days. Further, because operative results 16 years ago were not as favorable as those today, children selected for operation usually had the more severe form of disease. It is therefore not surprising that many of these children tended to have reduced exercise capacity. Another report[3] he cited more closely parallels his investigation, for that report concerned children admitted sequentially for cardiac catheterization between 1963 and 1967. Obviously, differences are still present, for his cases of "mild disease" were milder than ours in most instances. Further, his subjects were somewhat younger because his patients had been followed up under more ideal circumstances than those we were working under a number of years earlier. However, one can make general comparisons and I have therefore constructed Table I, which indicates the percent of children whose exercise endurance time fell below his 10th percentile and below our 3rd percentile.

TABLE I

Percent of Children Reported to Have a Lower Than Normal Endurance Time

	Prior Published Data	Cumming Study
VSD		
Mild	50	33
Moderate	50	22
Severe	90	81
ASD		
Mild	65	22
Moderate		27
Severe		43
PDA	15	13
Aortic stenosis		
Mild-moderate	47	28
Severe	55	31
Pulmonary stenosis		
Mild	47	16
Severe	50	40
Tetralogy of Fallot	95	86
Aortic insufficiency	25	38
Mitral insufficiency	43	38

ASD = atrial septal defect; PDA = patent ductus arteriosus; VSD = ventricular septal defect.

An examination of this table will indicate that, in most instances, the endurance time of a slightly higher percent of our patients than of his fell below normal. However, the differences are not great and because our definitions are not exactly comparable in many categories, the similarities are more impressive than the differences. Exceptions to this generalization include children with atrial septal defects and aortic stenosis. Figure 3 of our second paper[3] indicates that in many of our children with atrial septal defects endurance time fell only slightly below our 3rd percentile and that the curved slope was very steep at this point. Accordingly, in this category the data of the two studies appear further apart than was warranted by the actual situation. In view of the data reviewed in Table I, it is difficult to see how Cumming stated in the second sentence of his Introduction that "Goldberg et al. . . . reported that at least 80 percent of children with cardiac defects had a lower exercise capacity than that of normal children when tested with a progressive bicycle test."

I really doubt that we "stopped" the exercise test sooner than the test was stopped in the Canadian study for we rarely terminated an exercise examination. These examinations, as in the Cumming study, were terminated by the child's inability to continue. The mean maximal heart rate of our patients that Cumming referenced was that for a group of children with more severe forms of heart disease than those found in his sequential study of many children. Accordingly, the data for the two groups are not comparable.

Our data and conclusions are actually in general agreement with those of Cumming, and we congratulate him for an interesting and credible study. We certainly agree that mild forms of heart disease rarely cause a significant decrease in exercise capability, whereas severe disease is usually accompanied by marked degradation of exercise capacity. Perhaps our major disagreement with Cumming is that we do not be-

lieve that parents are accurate observers of a child's endurance other than at the extreme ends of the spectrum.

REPLY

The studies of Goldberg et al. were important because they were among the first to show that intense exercise was safe for most children with heart disease, but I found their results misleading in terms of what to expect for maximal heart rates and exercise capacities, and I still find the differences between his results and ours more striking than the similarities. In their Figure 6 of their early report (his Ref 2), 52 of 61 patients (over 80 percent) had an exercise capacity below the 3rd centile and this figure was reproduced in a chapter in the 1968 Moss-Adams book.[1] In their more recent study (his Ref 3), about 80 percent of their patients with cardiac defects had an exercise capacity below the median of the control group.

The level chosen for low fitness in the California studies was the 3rd centile, in ours the 10th, and this difference increases the comparative frequency of low fitness in our study. Even so, low fitness was recorded in 50 as opposed to 22 percent of patients with a moderate ventricular septal defect, 65 as opposed to 30 percent of patients with an atrial septal defect, 52 as opposed to 16 percent of patients with mild pulmonary stenosis, 50 as opposed to 28 percent of patients with mild aortic stenosis, comparing the California and Winnipeg series. Even greater differences are present when the frequency of fitness scores above the 50th centile are compared. Fitness scores above the median occurred in 5 percent as opposed to over 50 percent of patients with an atrial septal defect, 13 as opposed to over 50 percent of patients with a small or moderate ventricular septal defect, 10 as opposed to over 54 percent of patients with mild or moderate aortic stenosis and 5 as opposed to 35 percent of patients with mild or moderate pulmonary stenosis. These frequencies that differ by factors of 3-to 10-fold are hardly similar.

Goldberg correctly points out that disease severity may account for some of these differences, but in their first series 13 of 14 patients with an atrial septal defect had low fitness so that disease severity is not the only explanation. Other possible explanations include differences in the patient's past exercise habits and attitudes to exercise; source of the control group (school subjects are perhaps not ideal); differences occurring because one study used a bicycle and the other a treadmill; differences in age groups studied or body build patterns; differences in the design of the exercise protocol (and the Goldberg protocol has drawbacks, especially for young subjects); and differences in the goals set for the exercise technologists.

When Goldberg and his colleagues report that 69 percent of their patients had a maximal heart rate under 180 beats/min (his Ref 2) versus 11 percent of our patients, or that "randomly selected" patients with atrial and ventricular septal defects[2] had a near maximal heart rate of 178 versus 201 beats/min in our study, a reasonable conclusion is that several of the California patients could not be motivated to exercise close to maximal and that this might account for the observed differences between the two series. Our data clearly differ from his in the frequencies of low fitness and of high normal fitness in the patients with cardiac defects, and in their maximal heart rates, and I believe our data more accurately indicate the exercise capabilities of children with heart disease in our community, and likely most others. As for the parents of children with mild or moderate cardiac disease, most of those that I interview report that their children have normal activity patterns, and that is exactly what our treadmill studies showed.

DIAGNOSIS OF DISSECTING AORTIC ANEURYSM WITH SUPRASTERNAL ECHOCARDIOGRAPHY

Although we agree with Kasper et al.[1] that the suprasternal approach may be the best way to define the abnormality in aortic dissection, proper angulation of the transducer can allow visualization from a lower approach. We agree that the vibrating intimal flap is one of the most characteristic features of aortic dissection. This was first described—and its mechanism defined—in our own article,[2] of which the authors were apparently unaware.

REPLY

We are grateful to Nicholson and to Cobbs for pointing out that the vibrating aortic intimal flap is one of the most char-

acteristic features of aortic dissection and that the suprasternal approach is probably of advantage in defining the abnormality in aortic dissection. The aortic intimal flap could not be demonstrated from the lower approach in our case, despite multiple angulation. We appreciate that an appropriate precordial echocardiogram in some patients also allows visualization of aortic intimal flap, as obviously first described by Nicholson and Cobbs. We deeply regret that this was not mentioned in our article.

ESTIMATION OF PULMONARY VASCULAR RESISTANCE IN LEFT TO RIGHT SHUNT

Spooner et al.[1] recently undertook an echocardiographic examination of the relations of the ratios of the preejection period to ejection time of the right and left ventricles to pulmonary vascular resistance in children with a left to right shunt. They mentioned that they had confirmed our findings[2] that the right ventricular preejection period/ejection time ratio does not adequately predict a high pulmonary vascular resistance. They then went on to assess the value of dividing this right ventricular ratio by the similar left ventricular ratio (abbreviated to R/L), and found that, although this also did not correlate well with pulmonary vascular resistance, the R/L ratio correlated very well with the pulmonary/systemic resistance ratio. As a result they concluded that: " . . . the use of the regression equations described should allow at least a rough estimation of pulmonary arteriolar resistance/systemic arteriolar resistance . . . This should prove useful to clinicians in the timing, or avoidance altogether, of cardiac catheterization with its attendant risks and expense." Unfortunately, these conclusions are not warranted for several reasons.

1. It is not clear that a resistance ratio is useful in evaluating whether any given pulmonary vascular resistance will permit surgery to be performed safely. Systemic vascular resistance is labile; it averages 20 Wood units/m^2 body surface area, but varies from 10 to 30 units with fever, anemia, anxiety, heart failure or deep sedation. A resistance ratio of 0.5 might be found if pulmonary and systemic arteriolar resistances are, respectively, either 10 and 20 units or 5 and 10 units. The outlook for successful surgery is worse in a child with the first than with the second set of numbers.[3] This issue is particularly important when the two circulations are separated by surgical closure of the defect, because then it is the absolute pulmonary arteriolar resistance that is important for postoperative right ventricular function.

2. Even if the resistance ratio is worth considering, there are reasons to doubt that it can be predicted accurately in individual patients.

A. In the study of Spooner et al. the range of resistance ratios examined did not cover evenly the values of interest. Of the 25 patients studied, 17 had a low resistance ratio below 0.2 and only 2 had a ratio greater than 0.5 at which surgical closure of the defect might be contraindicated. One of these two had a very high ratio of 2.35, and the values for this patient will have a disproportionate weight in the regression analyses.

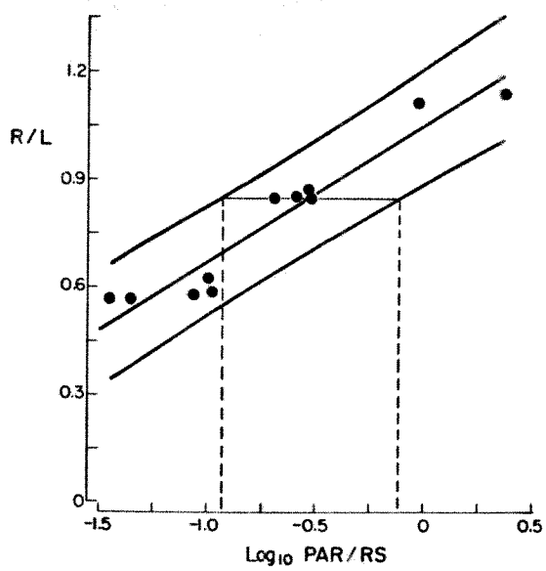

FIGURE A. Regression line and 95 percent confidence limits for relating the R/L ratio (Y axis) to the logarithm of the pulmonary arteriolar resistance/systemic arteriolar resistance PAR/RS ratio (X axis). For any given R/L ratio, as defined by the horizontal line, the 95 percent confidence limits of the log PAR/RS ratio are very wide, as shown by the interval between the **dashed vertical lines**.

B. The regression analysis was performed with the wrong axes. It is not reasonable to regard the resistance ratio as being dependent on the R/L ratio and, in fact, the basis of the method is that ventricular contraction and ejection times depend on the peripheral resistances and pressures. As a result, the pulmonary arteriolar resistance/systemic arteriolar resistance (PAR/RS) ratio (or its logarithm) should be plotted on the X axis and the R/L ratio on the Y axis.

This is not just an academic issue for two reasons. First, the least squares method of fitting a regression line minimizes the vertical deviations of the Y values from the regression line, so that it matters which set of data is chosen as the Y variable. Second, by using the correct axes, prediction of the resistance ratio (X) from the R/L ratio (Y) must be made by inverse prediction, as we[2] have pointed out before.

C. Most important of all, a high correlation coefficient—even one as high as 0.960—is no guarantee that single values drawn from this population can be predicted accurately. The data in their Table I can be used to calculate the standard deviation from the regression line for the 11 children with ventricular septal defects or endocardial cushion defects (Fig. A). This value was 0.062, a relatively large value (about 10 percent of the mean value). The importance of selecting the correct axes and of defining the confidence limits by inverse prediction are shown in Table I, which features the data for these 11 children. Thus, for patient 21 with an R/L ratio of 0.842, the 95 percent confidence limits range from a resistance ratio of 0.12 to one of 0.78, a range too large to be of value in individual patients. Furthermore, because of the logarithmic scale, higher R/L ratios will be associated with greater 95 percent confidence ranges for the resistance ratio. Therefore, the R/L ratio will be least useful where it is most needed.

The fallacy comes from paying attention only to the correlation coefficient, which at best gives information about group prediction, and not calculating the 95 percent confidence limits, which give information about the accuracy of prediction for single patients. As a result, the authors have ignored the fact that the confidence limits for this relation of

the R/L ratio to the pulmonary/systemic resistance ratio are too wide to provide accurate enough information to influence the decision to perform cardiac catheterization, especially since a wrong decision might have disastrous consequences for the individual patient.

Julien I. E. Hoffman, MD, FACC

REPLY

1. A child with a resistance ratio of 0.5 and pulmonary resistance of 10 units is at greater risk than one with the same resistance ratio and a pulmonary resistance of 5 units. However, the pulmonary vascular resistance is just as labile as the systemic, if not more so, and is affected by the same variables to which they refer. In addition, as stated in our article, because estimated oxygen consumption values are used by most laboratories, a large additional error of up to 40 percent may be introduced into the calculations. I therefore disagree with the implication that it is doubtful that "the resistance ratio is worth considering," especially as virtually all cardiologists, including Hoffman and Silverman (M.A. Farina, personal communication) do at least *consider* it, along with other variables, in preoperative evaluations. However, it should not be the *sole* consideration, and we did not mean to imply otherwise.

2A. I agree that the resistance ratios examined did not evenly cover the range of interest. This is as expected, since it is the aim of most pediatric cardiologists to keep resistance ratios within normal limits, and the patients were studied at random. Certainly, an equal number of very high and very low ratios would raise suspicions about the quality of care being rendered. Nonetheless, even when the data points for the two patients with highest resistance ratios are removed, the correlation coefficient remains high, at 0.84.

2B. I agree that the axes are incorrect. When the paper was originally submitted, the axes were reversed from those published, and only the illustrations were changed at the reviewer's insistence. The regression analyses were done originally from the correct axes, were made by inverse prediction and were unchanged in the revised version that was eventually published (see Fig. 1).

2C. Hoffman and Silverman state that the confidence limits for the relation of R/L to the pulmonary/systemic resistance ratios are too wide and provide a figure with calculated 95 percent confidence limits based on only 11 of our total group of 25 patients (those with ventricular septal defect) to support this conclusion. The fact that only 11 patients produce very wide confidence limits is unquestioned, because the width of these limits varies inversely with the size of the patient population. We alluded to this in the paper by stating, "A much larger patient population would improve the confidence limits and will be reported on when patient data have been acquired and analyzed." Although restriction of the group to those 11 for calculation of confidence limits is perhaps warranted because they are the group pediatric cardiologists would be most interested in, there is no doubt the confidence limits are narrower using the entire population. Even so, I believe the 95 percent confidence limits given by Hoffman and Silverman have been miscalculated. Confidence limits for future predictions of Y from an observed X do not form two parallel lines, as shown in their figure, but rather two opposing hyperbolae, whose apexes converge at the mean X of the data and diverge at the extremes of data. This is intuitively reasonable, because one would expect that the "best" predictions

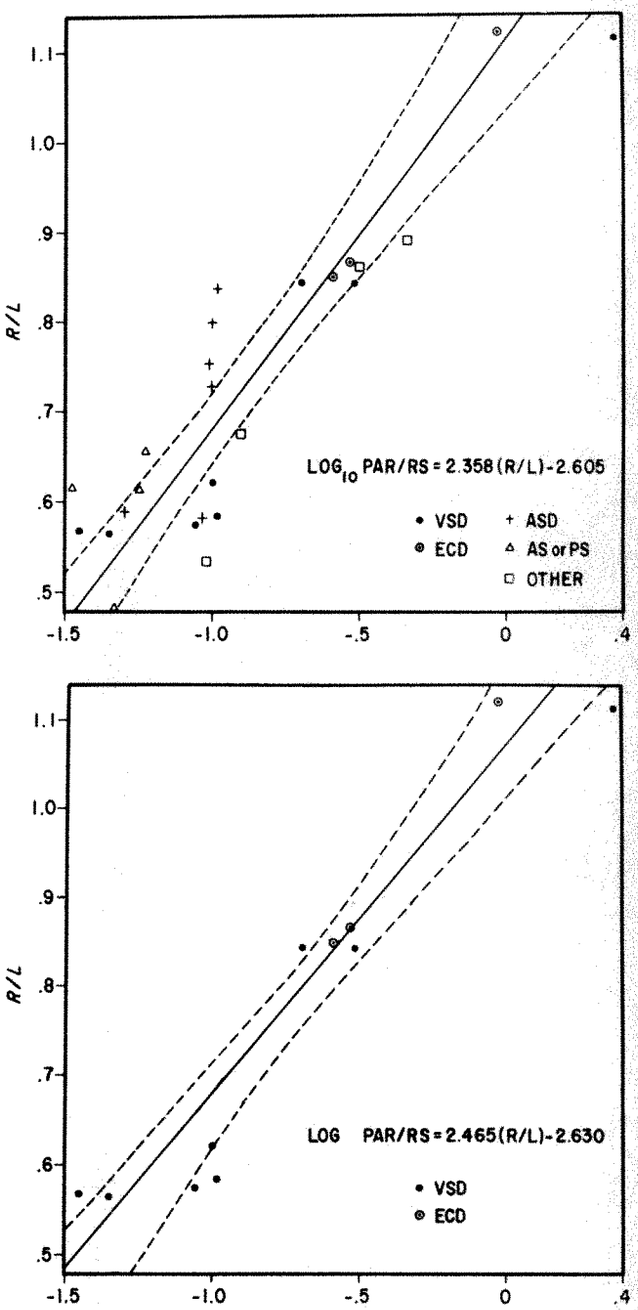

FIGURE 1. Plot of R/L versus PAR/RS and calculated 95 percent confidence limits for future predictions of PAR/RS for the total group of 25 patients (**top**) and the 11 patients with ventricular septal defect (**bottom**). AS or PS = aortic or pulmonary stenosis; ASD = atrial septal defect; ECD = endocardial cushion defect; VSD = ventricular septal defect.

of future events would be made in the "middle" of the data, and that the predictions would be "less good" away from the middle and become quite poor outside the observed range.[1]

The 95 percent confidence limits for an observed X_K are given as

$$\pm 2.069 \sqrt{S^2 \left[\frac{1}{n} + \frac{(X_k - \overline{X})^2}{\sum (X_i - \overline{X})^2}\right]}$$

The plot of R/L versus PAR/RS, together with calculated 95 percent confidence limits for future predictions of PAR/RS (not for the population data) are shown in Figure 1 for all 25 patients (top) and for those 11 patients with ventricular septal defects (bottom). As can be seen, these are much narrower than those shown by Hoffman and Silverman and form hyperbolae.

Again using Patient 21, and the confidence limits for the 11 patients only, with R/L = 0.842, the predicted $\log_{10}$ PAR/RS = 0.554 ± 0.105 (95 percent confidence limits), $\log_{10}$ PAR/RS lies between −0.449 and −0.659 ($p > 0.95$) and PAR/RS lies between 0.22 and 0.35 ($p > 0.95$) where the actual value was 0.301. This is rather different from their calculated range of 0.12 to 0.78, which appears to have been calculated using twice the standard error about the regression.

Again, I reiterate that "the use of the regression equations should allow at least a rough estimation of PAR/RS," but in no way should it be used as the *sole* criterion in timing of cardiac catheterization.

FAILURE OF PROPHYLAXIS FOR BACTERIAL ENDOCARDITIS: AMERICAN HEART ASSOCIATION REGISTRY

The American Heart Association (AHA) recognizes that its current recommendations for antibiotic prophylaxis are necessarily empiric.[1] This situation has arisen because important clinical information on the efficacy of antibiotic prophylaxis of bacterial endocarditis is lacking. The present recommendations are therefore based upon secondary sources of information such as the relative propensity of various procedures to cause bacteremia, *in vitro* studies of bacteria recovered from the blood, the effect of antibiotics on bacteremias, the susceptibility of various heart lesions to infection, anecdotal case reports, and study of experimental models.

Although over 30 individual cases of apparent prophylaxis failure have been recorded in the literature, many of our colleagues have rightly pointed out that the evidence indicating that a significant number of prophylaxis failures actually occur is inconclusive. This question is of considerable medical and medicolegal importance because of the frequency with which measures to prevent endocarditis are called for, and because of the serious consequences of failure to prevent the disease.

In an attempt to accumulate useful epidemiologic data, the AHA Committee has established a Registry to record cases of apparent failure of antibiotic prophylaxis of bacterial endocarditis. We are now soliciting case reports. Notification may be made on a simple pre-printed postcard, which will require only identification of the patient and the name, address, and telephone number of the person referring the case. These postcards will be made available to physicians and dentists and to any other person or organization requesting them from the AHA or from one of us. Alternatively, a case may be reported directly to one of us, at the address or telephone number listed below. After notification, one of us will follow up with a telephone call, in order to gather sufficient information to evaluate the case. All such information will be confidential.

Although there are obvious disadvantages to any retrospective evaluation such as this, the practical impossibility of conducting a prospective trial of different modes of prophylaxis has caused us to seek alternative means of gathering data. We hope that a useful body of information may be accumulated, which may influence future recommendations for prophylaxis of endocarditis.

CORONARY ANGIOGRAPHY: PHYSICIANS' RESPONSIBILITY

A specter is haunting cardiology—the specter of malpractice, conjured forth in these pages by Effler and Gensini.[1] They propose that when coronary heart disease must be ruled in or out coronary arteriography is "the sine qua non of diagnosis" and, moreover, that all patients have a legal right to know that

this technique "may be available and helpful." They then set up a straw rejoinder—"We cannot catheterize *everybody*"—and knock it down with: ". . .few of our good cardiovascular laboratories are taxed beyond their productivity." Thus, according to Effler and Gensini: (1) All patients with actual or suspected coronary disease are entitled to angiography; (2) there are enough good catheterization laboratories to do this Herculean labor; moreover, (3) each patient must be advised to the technique to absolve the "traditional cardiologist" of his "tyrannical (*sic*) role" in decision making.

In observing that the patient's right to know the options available "constitutes a basic (*sic*) ethic," Effler and Gensini consider inevitable a "landmark malpractice decision against a cardiologist" on behalf of a patient "not informed of options in diagnosis and therapy of coronary artery disease."[1]

Our distinguished colleagues' modest proposal has some of the allure of a dead mackerel in the moonlight—it shines, but when you get close you have to hold your nose. One need not necessarily agree with some keen observers who might smell an effort to drum up business.[2] Indeed, we cannot fault their intentions if their proposal springs rather from professional zeal based on belief in the absolute value of this test and humanitarian zeal for the patient's rights and their own ethical conduct. Even a scientific argument could be made for what their advocacy clearly implies—a mandatory offer of coronary arteriography. Yet they must first deal with a few nagging considerations that may trouble even some of us non-"traditional cardiologists": (1) How broad and how deep is "the right to know"? Although we always get *advised* consent, how informed is "*informed* consent" when the consenter is at a factual and psychologic disadvantage and, if confronted by an informed zealot, a tactical disadvantage? (2) The relatively small but definite complication and death rates of the procedure are not equal in all catheterization laboratories. Is not the patient legally or at least—as a "basic" ethic—entitled to minimal risk? Will he have an equal right to first compare the safety record of all the available labs? (3) As Gensini contends for the Veterans Administration Cooperative Trial, the technical quality of angiograms is far from equal among laboratories. Should not the patient be informed (by right) of this gross inequality of product? (4) Even in our leading institutions, there is enormous observer variability in interpreting coronary angiograms, particularly for the vast spread of disease between 0 and 100 percent occlusion.[3] Whose reading should prevail? (5) Is a single angiogram enough? How often will repeat angiograms be mandated—by law or by ethics?—to follow the dynamics of coronary atherosclerosis (bypassed or not)? After all, we are ethically bound to a *perpetual* defense of the patient's health and rights. (6) Distinguished surgeon and distinguished angiographer, Effler and Gensini restrict the legal and ethical legerdemain in their proposal to the single diagnostic procedure that they themselves are most concerned with. If they are dealing with a principle—scientific, ethical or legal—this restriction is illogical and smacks of advocacy. Should not we all therefore maintain up to date checklists of *every* available diagnostic and therapeutic modality so that nothing might be omitted in terror of a nit-picking lawyer? (7) Should not the patient's right to know pertain to the quality as well as the quantity of what he is informed (advised) of? Will the information (including any controversial aspects) be presented matter-of-factly or do well meaning zealots now have a legal mandate to transmit their enthusiasm? We have decades of experience with worthless and dubious treatments for coronary disease, breast cancer, duodenal ulcers, and so on, all "sold" to the patient by those quite honestly believing in their value. Effler may recall advocacy of the Vineberg operation, specifically including the attendant arteriography.[4] The Vineberg procedure had only uncontrolled trials but was finally discredited after follow-up.[5] Uncontrolled surgical trials are inherently unethical[6–8] and thus malpractice at best—assault and battery at worst. If Effler and Gensini have now nudged us into more legal thickets, perhaps they will tackle all these issues constructively.

So much for the *shiny* side of this mackerel-by-moonlight. Its aroma arises, not so much from an inadequate presentation of a serious issue, but rather from the objectionable and threatening aura of this presentation. Thus, our colleagues' letter is both incomplete and, on at least four grounds, unseemly. First, it is unseemly because Effler and Gensini raise the specter of malpractice suits based on coronary patients who die in ignorance of coronary arteriography. The malpractice threat may be real—hereafter at least—so that on legal as well as logical and humanitarian grounds they should not have ignored the issues raised in the preceding paragraph. Second, these authors remind us of ethical changes in practice (e.g., informed consent) based on "dramatic social changes." Cardiologists are quite aware of this and need not be lectured on ethics by chronic advocates of therapies (Vineberg operations, coronary bypass grafting) before their scientific—hence, ethical[6–8]—validation by appropriately designed controlled clinical trials. Third, their description of "the traditional cardiologists' . . . tyrannical role" is more than unseemly; it is egregiously insulting. Considering its source, this unfounded generalization is worthy of Uriah Heep—traditional surgeons and directors of catheterization laboratories, of course, being total strangers to tyrannical roles. Finally, the assertion of underutilization of our "good" laboratories as an inducement to universal coronary arteriography suggests a ghastly variant of Parkinson's law: Let the work expand to fill the facilities. In Britain, with comparable demography, there is a comparative dearth of laboratory and surgical facilities, despite which mortality indexes and other statistics are comparatively good.[9]

On performance, Effler and Gensini are at the pinnacle of their craft. Hence, to use the analogy of Linus Pauling and Vitamin C, any proposal by them must be considered seriously. On performance, they are clearly capable of a much better presentation of this proposal on its merits. But, on performance, they are ill suited to lecturing us on ethics and hectoring us on malpractice.

REPLY

There seems to be little doubt that our letter, "Miranda and the Patient with Coronary Disease," raised the hackles of David Spodick and provoked a rather lengthy rebuttal. We have reread it a number of times and fail to see the reason it should upset anyone. Perhaps we look upon it in the same way that doting parents look upon their homely child.

The letter tries to make several points:

1. Coronary cinearteriography is the ultimate diagnostic procedure for coronary artery disease; yet, it is used too selectively or not at all by many clinical cardiologists.
2. A basic ethic of medical practice requires that the physician advise a patient of his options for diagnosis and therapy; we did not invent this ethic but submit that it does exist. A recent medical-legal report by Winslade[1] states that patients are becoming more demanding consumers, more vociferously expressing dissatisfaction and more often filing law suits for malpractice. The California Supreme Court and several other State Courts have clearly stated that physicians must inform patients, in understandable layman's language, about the nature of their conditions, the methods of treatment, including *available alternative forms of treatment*, and the risks inherent in each. The patient, not the physician, has a right and responsibility to weigh the potential benefits and risk of treatments and to decide whether—and if so, which—treatment should be employed.

Like it or not, we do live in a time when litigation is a specter that haunts everyone who practices clinical medicine and surgery. Surgeons were the first to feel the hot breath of plaintiff lawyers and are most careful to obtain informed consent and offer the right to second opinion. Apparently there are still many cardiologists who do not give the patient with coronary disease much choice in the matters of diagnosis and therapy but have taken full responsibility for this upon themselves. There are cardiologists who think little of coronary cinearteriography and want nothing to do with myocardial revascularization surgery. Such attitudes do not concern us particularly but we do believe that the patient with ischemic heart disease has a right to know his options and that is the sole reason for the "Miranda" letter. Several critics have suggested that by putting these points in print we may be encouraging legal action against practicing cardiologists; that is not our intent. In our part of the country there is always an impatient skater who can't wait to go through thin ice and immerse himself in hypothermic waters. If he insists upon taking such a risk he has no right to resent the individual who posted the sign "Danger—Thin Ice"!

MANAGEMENT OF PERICARDIAL EFFUSION

The article by Wei et al.[1] contains several misconceptions and errors of fact, and their technique may represent regression rather than progress in the diagnosis and treatment of pericardial effusion.

As the authors state, arrhythmias, cardiac perforation or coronary laceration are potential (and common) complications of pericardiocentesis. Since the initial step is blind insertion of a no. 18 Seldinger needle, the authors' technique involves the same potential complications. The xiphisternal route most certainly does not avoid the pleurae, which in many patients cross the mid line with inspiration, or major coronary arteries, since the acute marginal branch of the right coronary is often directly in the path of the needle. In addition, since the needle aims toward the thin-walled right ventricle, perforation may easily occur at the same time that a current of injury appears in the electrocardiogram.[2] An experience with only three patients does not document the safety of this technique; although no one is going to report their "series" of disastrous complications with pericardiocentesis, most experienced cardiologists and cardiac surgeons have seen death from pericardiocentesis at least once.[3] And when the procedure itself does not cause harm, the delay in providing adequate decompression of the pericardial sac may do so.

The authors appear to have a hangup regarding the morbidity of general anesthesia and thoracotomy. This concern is inappropriate. Operative decompression of the pericardium can be performed thru a subxiphoid approach, often under local anesthesia. When general anesthesia is necessary it may be a light anesthesia not requiring intubation. The entire operation takes 30 minutes, allows direct vision of the sac and heart and placement of one or more large bore chest tubes in perfect position at zero risk. This is not a thoracotomy because the pleural spaces are not violated. I am uncertain what the authors mean by "morbidity of surgical procedures," but the operative approach is extremely well tolerated and, other than the presence of a small scar, produces no more morbidity than pericardiocentesis. The notion that critically ill patients should first have pericardiocentesis before being considered for surgery is erroneous. It is precisely the critically ill patients who should go immediately to surgery, rather than incur further delay with misguided (how appropriate a term) attempts at pericardiocentesis.

In an excellent and thoughtful article, referred to by Wei et al., Kilpatrick and Chapman (two internists) all but buried pericardiocentesis in favor of direct operative intervention,[3] and this was published long before operation was made even safer by the subxiphoid approach. In a popular textbook another internist has condemned pericardiocentesis[4] for all but the emergency relief of tamponade (and again I disagree with this indication also). The safety (46 cases without mortality) of the subxiphoid approach in our own institution was recently documented by my colleagues,[5] confirming earlier reports from many institutions regarding the efficacy of this technique. The authors have presented an improvement in the technique of pericardiocentesis but I believe the entire procedure should be abandoned in favor of the safer and more reliable approach of surgical intervention.

REPLY

We have no quarrel with Becker's position that surgical decompression of a pericardial effusion is safe and effective, and that in many instances it is the procedure of choice for both diagnostic and therapeutic purposes. Situations arise, however, when progressive cardiac tamponade becomes life-threatening and urgent drainage of the pericardial fluid is mandatory. With appropriate hemodynamic monitoring in an intensive care unit and an experienced physician performing the procedure, pericardiocentesis can be accomplished quite safely. Two recent series, encompassing 105 patients (many with repeated pericardiocenteses) without serious complications attest to the safety of current techniques in skilled hands.[1,2] Echocardiographic proof of effusion is, of course, obligatory and we suspect that older reports, such as emphasizing the dangers of that of Kilpatrick and Chapman's periocardiocentesis included patients in whom the procedure was done for diagnostic purposes where there was little, if any, free effusion.

Our technique of pigtail catheter drainage of large pericardial effusions was designed as a temporizing measure in patients destined for surgery. Given the choice, we daresay most surgeons and anesthesiologists prefer to work with patients with cardiac tamponade in a hemodynamically stable condition and on a relatively elective basis. Our technique provides time for such stabilization and planning. An additional benefit which we had not originally envisaged is that radiotherapy (malignant effusions) or instillation of local chemotherapeutic agents through the pigtail catheter (uremic or malignant effusions) may provide completely satisfactory treatment of the problem without the need for surgery. Two reports published after our article involving larger series of patients support this view.[2,3]

The technique of needle, catheter or surgical drainage of pericardial effusions each has inherent risks and benefits that need to be considered carefully in individual patients according to the particular clinical situation. We do not champion our technique to the exclusion of the others and we have no desire that Becker's surgical approach be "buried," "condemned" or "abandoned."

29TH ANNUAL SCIENTIFIC SESSION

AMERICAN COLLEGE OF CARDIOLOGY

HOUSTON, TEXAS MARCH 9–13, 1980

CALENDAR OF EXTRAMURAL PROGRAMS

The aim of each program is to increase the theoretical and practical knowledge of the normal and abnormal function of the cardiovascular system in man. Most of the programs are pertinent to direct care of patients with heart disease. The need for such programs increases with the ever increasing amount of scientific and clinical data, the constant changes in technology and methodology, and the greater availability of therapeutic options. Today most cardiologists, internists and family practitioners feel the need of supplementing their professional reading by direct contact with the authors, research workers and leaders in the field.

To solve these problems the Committee selects each year series of carefully supervised programs which are usually preceded by extensive consultations with the program directors recruited among the foremost specialists educators and scientists in the field of clinical cardiology and allied basic science disciplines.

Although each program director is personally responsible for the choice of faculty, and the structure of the program, the National Committee of Continuing Education assumes the overall responsibility for the caliber of the postgraduate education and the relevance to the practice of cardiology. This is accomplished by the processes of meticulous scrutiny of the objectives, analysis of the educational methods, and studying the impact of each course on the knowledge and attitudes of the participants.

These programs should help each physician to keep up with the new knowledge, to put into practice the new advances and to retract gracefully from the obsolete and useless practices. An effective practitioner must learn and relearn, listen to new ideas, share past experiences and observe the work of his peers. The National Program Committee for Continuing Medical Education of the American College of Cardiology believes that these goals can be accomplished by all members and nonmember professionals participating in our continuing education programs.

Leonard S. Dreifus, MD, FACC
Chairman, Continuing Education Committee for Extramural Programs

Programs and faculty are subject to change. For further information write Registration Secretary, Extramural Programs Department, American College of Cardiology, Heart House, 9111 Old Georgetown Road, Bethesda, Maryland 20014.

JANUARY THROUGH MAY 1980

To be arranged individually — **Preceptorships in Cardiology.** Arthur Seizer, FACC, director, Pacific Medical Center, San Francisco, CA

To be arranged individually — **Preceptorships in Cardiology.** Jules Constant, FACC, director, Buffalo General Hospital, Buffalo, NY

JAN. 14–18 — **Eleventh Annual Cardiovascular Conference at Snowmass.** John H. K. Vogel, FACC, director and Bruce C. Paton, FACC, co-director. Snowmass Resort, Snowmass, CO

JAN. 15 — **Coronary Artery Disease: Diagnosis and Treatment.** William C. Sheldon, FACC and J. Kent Trinkle, directors. Convention Center, San Antonio, TX

JAN.31–FEB. 2 — **Fundamentals of Echocardiography—An Introductory Course for Clinicians.** Joseph K. Perloff, FACC, director and Pravin M. Shah, FACC and John S. Child, FACC, co-directors. Century Plaza Hotel, Los Angeles, CA

FEB. 13–15 — **Cardiac Diagnosis: Reappraisal of Established Techniques and the Place for New Techniques.** Ralph Shabetai, FACC, John Ross, Jr., FACC, Gabriel Gregoratos, FACC and Joel S. Karliner, FACC, directors. Vacation Village Hotel, San Diego, CA

MAR. 24–28 — **Thirteenth Annual Seminar. Electrocardiographic Interpretation of Complex Arrhythmias: A Physiological Approach.** Charles Fisch, FACC and Douglas P. Zipes, FACC, directors. Indiana University Medical Center, Indianapolis, IN

APR. 7–16 — **Cardiology for the Consultant: A Clinician's Retreat.** E. Grey Dimond, FACC and James E. Crockett, FACC, directors. Rancho Santa Fe Inn, Rancho Santa Fe, CA

APR. 10–13 — **Current Concepts and Advances in Diagnosis, Management and Prevention of Cardiac and Cardiopulmonary Diseases.** James S. Forrester, FACC, director. Los Angeles, CA

APR. 14–18 — **Consultant's Course in Cardiology.** Michael V. Herman, FACC, Louis E. Teichholz, FACC, Richard Gorlin, FACC, Simon Dack, FACC and Ephraim Donoso, directors. Mt. Sinai Medical Center, New York, NY

APR. 16–18 — **Vectorcardiography—Basic Workshop.** Alberto Benchimol, FACC, director. Scottsdale Hilton Hotel, Scottsdale, AZ

APR. 21–23 — **Practical Cardiology for the Family Physician.** Robert S. Eliot, FACC, director. Marriott Hotel, San Antonio, TX

APR. 24–26 — **The Pathology of Congenital Heart Disease.** Jesse E. Edwards, FACC, Saroja Bharati, FACC and Maurice Lev, FACC, directors. Palmer House, Chicago, IL

APR. 25–27 — **New Concepts in Clinical Electrocardiography.** William J. Mandel, FACC and Irwin Hoffman, FACC, directors. Beverly Hilton Hotel, Beverly Hills, CA

May 1–3 — **Problems in Management of Valvular and Ischemic Heart Disease.** Leonard G. Christie, Jr., FACC, Carl J. Pepine, FACC and C. Richard Conti, FACC, directors. Harstan Convention Center, Innisbrook Resort and Golf Club, Tarpon Springs, FL

MAY 3–6 — **Fifth Annual Symposium on Cardiovascular Nursing.** Henry J. L. Marriott, FACC and Leo Schamroth, FACC, directors. Carillon Hotel, Miami Beach, FL

MAY 7–9 — **Clinical Auscultation of the Heart.** W. Proctor Harvey, FACC, director and Antonio C. deLeon, Jr., FACC and John F. Stapleton, co-directors. Georgetown University Medical Center, Washington, DC

MAY 12–14 — **Trends in Cardiology.** J. Willis Hurst, FACC, director and Robert C. Schlant, FACC, co-director. Sheraton Atlanta Hotel, Atlanta, GA

MAY 15–17 — **Acute Myocardial Infarction.** Arthur Selzer, FACC and Keith E. Cohn, FACC, directors. The St. Francis Hotel, San Francisco, CA

MAY 21–23 — **Diagnosis and Treatment of Dysrhythmias in Children.** Paul C. Gillette, FACC, Arthur Garson, Jr. and Dan G. McNamara, FACC, directors. Texas Children's Hospital, Houston, TX

LEARNING CENTER: PROGRAM CALENDAR

The American College of Cardiology's newest department, the Learning Center, located at the College's Bethesda Maryland headquarters, began operations in October 1977 with the offering of its first continuing medical education program for physicians with a specialty or an interest in cardiovascular medicine. The purpose of the Learning Center is to support the professional commitment to quality patient care by providing a new standard of excellence in cardiovascular continuing education. For additional information concerning the programs listed below or for a complete schedule of programs through July 1980, contact Program Coordinator, Learning Center, American College of Cardiology, 9111 Old Georgetown Road, Bethesda, Maryland 20014. Telephone (301) 897-5400.

JANUARY THROUGH JULY 1980

Month/Dates	Program Director	Title of Program
Jan. 21–23	William C. Roberts, MD	**Congenital Heart Disease: The Multidisciplinary Approach**
Jan. 28–30	Gottlieb Friesinger, MD	**Surgery in Ischemic Heart Disease**
Feb. 6–8	Bertram Pitt, MD	**Nuclear Cardiology**
Feb. 11–13	Melvin L. Marcus, MD	**New Approaches to the Short and Long Term Treatment of Myocardial Infarction**
Feb. 18–20	Roger A. Winkle, MD	**Antiarrhythmic Therapy: Current Status and Future Promise**
March 24–26	John A. Mantle, MD	**Quality Assurance and Management for Cardiovascular Nurses**
March 27–29	John Spittell, MD	**Peripheral Vascular Disease**
April 9–11	Victor Parsonnet, MD	**Current Concepts in Pacing**
April 14–16	Keith Cohn, MD	**Exercise Testing**
April 21–23	Nanette Wenger, MD	**Rehabilitation of the Cardiac Patient**
April 28–30	Pravin M. Shah, MD	**M-Mode and 2-Dimensional Echocardiography: Current Status and Future Promise**
May 1–3	Daniel S. Berman, MD	**Nuclear Cardiology**
May 5–7	Robert G. Tancredi, MD	**Pulmonary, Renal and Electrolyte Considerations in Cardiovascular Disease**
May 12–14	Louis Lemberg, MD	**CCU Update for Nursing Supervisors**
May 19–21	Arthur E. Weyman, MD	**Cross-Sectional Echocardiography**
May 28–30	Elliot Rapaport, MD	**Cardiology for the Consultant**
June 2–4	Borys Surawicz, MD	**Advanced Cardiac Electrophysiology**
June 16–18	Sylvan Lee Weinberg, MD	**CCU Update for Nursing Supervisors**
July 14–16	Arthur D. Hagan, MD	**Fundamentals of Clinical Echocardiography for the Non-Echocardiographer**
July 24–26	Victor F. Froelicher, Jr., MD and Paul L. Henry, MD	**Exercise Testing**

AMERICAN COLLEGE OF CARDIOLOGY

Announces . . .

AFFILIATE IN TRAINING MEMBERSHIP

For Physicians in Cardiovascular Related Training Programs

Candidates for this membership category must be current full-time trainees in a recognized cardiovascular (adult, pediatric, surgical) related program in fulfillment of requirements for admission to a subspecialty board examination which holds membership in the American Board of Medical Specialties. Upon completion of training and in order to maintain an affiliation with the College, the members are encouraged to apply to the Credentials Committee for status in one of the other three membership categories.

The application for Affiliate in Training must be signed by the Director of the applicant's training program and two sponsors, both of whom must be Fellows of the College. One of the sponsors may be the Director of the training program, provided he is a Fellow of the College. The annual dues for an Affiliate in Training are $25.00.

Advantages to the Affiliate in Training

1. Subscription to *The American Journal of Cardiology,* the official journal of the College.
2. Reduced fees for all educational programs of the College.
3. Preference for enrollment in programs sponsored by the College with a limited registration.
4. Receipt of the quarterly publication, *Cardiology,* the newsletter of the College.
5. Participation in all affairs of the College as a member rather than as a guest of the College.

Those desiring an application form should write to Ms. Margaret E. Coffey, Director, Membership Department, American College of Cardiology, 9111 Old Georgetown Road, Bethesda, Maryland 20014.

INSTRUCTIONS FOR AUTHORS

The editors of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- Address manuscript to Managing Editor, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- Submit two copies of all elements of the article: text, references, legends, tables and figures.
- Arrange the paper in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- Number all pages in above sequence, beginning with title page as 1, abstract as 2, etc.
- Type all matter: (1) on $8\frac{1}{2} \times 11$ opaque white bond paper; (2) in duplicate; (3) on one side of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- Include first names, degrees and, where applicable, FACC for all authors.
- Provide a short running title of 3 to 6 words.
- Insert at bottom: name and address of institution from which work originated plus information about grants.
- Add at bottom the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- Limit words as follows: 100 to 250 words for major articles; 50 to 100 words for case reports.
- Add at end of abstract: list of 2 to 6 key words and subjects for indexing.

THE TEXT

- Type in duplicate; double-space.
- Do not use abbreviations such as SVC, WPW: write out superior vena cava, Wolff-Parkinson-White.
- Abbreviate measurements (mm, kcal and the like) as recommended in *Uniform Requirements for Manuscripts Submitted to Biomedical Journals*, published in *Am Rev Respir Dis* 1979; 119:3–10; *Ann Intern Med* 1979; 90:95–9; *Br Med J* 1979; 1:532–5; and *Lancet* 1979:1:428–30.
- Cite in numerical order every reference, figure and table. (Order of mention in text determines the number given to each.)
- Place acknowledgments at end of text, before references.

THE REFERENCES

- Type in duplicate; double-space.
- Number the references in order in which they are mentioned in text.
- Provide concluding page numbers for all journal references and specific page numbers for all book references. Indicate all abstracts by the abbreviation (abstr).
- Follow the general arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- Start at top of new page.
- Type in duplicate; double-space.
- Identify at the end of each legend and in alphabetical order all abbreviations in the figure described.

THE TABLES

- Start each table at top of new page.
- Type in duplicate; double-space.
- Give each table a number (in roman numerals: Table I, II, etc) and a title. Number the tables in order in which they are mentioned in the text.
- Provide a footnote to each table—identifying in alphabetical order all abbreviations used.

THE FIGURES

- Submit 2 glossy prints (not originals) of each photo and drawing.
- Please note that art work of published articles will not be returned.
- Use black ink for all charts (line drawings) Make decimals, broken lines, etc. strong enough for reproduction.
- Use arrows to designate special features.
- Crop photomicrographs to show only essential field.
- Identify figures on back by number and author's name.
- Number figures in order in which they are mentioned in the text.
- Indicate top of each figure.
- Submit written permission from publisher and author to reproduce any previously published figures.
- Limit figures to number necessary for clarity. The publisher allows a limited sum toward reproduction.

Examples of Styles of References

For periodicals, follow INDEX MEDICUS, listing *all* authors (if there are 7 or more, list only 3 and add et al.):

31. Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 1027–34.

(Author: please note that no periods are used after authors initials)

For chapter in book:

28. Schiebler GL, Van Mierop LHS, Krovetz LJ. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968:134–9.

For books (personal author or authors):

36. Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

(Author: all book references should have specific page numbers.)

Four more reasons why we're the number one name in medical publishing.

Beeson, McDermott & Wyngaarden

CECIL TEXTBOOK OF MEDICINE

15th Edition

This year the only thing bigger than the name is the coverage. A new editor, several new parts, and a careful revision make this fifteenth edition the most important and up-to-date yet. You'll find exciting new material on human growth and development, critical care medicine, drug interactions and much more. Order now!

By **Paul B. Beeson**, MD, **Walsh McDermott**, MD, and **James B. Wyngaarden**, MD. 2,478 pp. 235 ill. (9 in color). Single volume: $46.00. **Order #1663-1.** 2-vol. set: $56.00. **Order #1667-4.**

Rich & Spencer

VASCULAR TRAUMA

This book gives detailed descriptions of a number of vascular injuries, including a thorough review of their history, incidence and nature. Authoritatively presented, it contains a wealth of historical, statistical, and clinical information describing the etiology, pathology, diagnostic methods, management, results, and follow-up of a variety of arterial and venous injuries. Major vessels are emphasized.

By **Norman M. Rich**, MD, FACS, Col.; MC, USA, Chief, Peripheral Vascular Surgery Service, Walter Reed Army Medical Center; Prof. and Chairman of the Dept. of Surgery, Uniformed Services Univ. of the Health Sciences; and **Frank C. Spencer**, MD, FACS, George David Stewart Prof. of Surgery and Chairman of Surgery Dept., New York Univ. School of Medicine. 610 pp. 563 ill. $42.00. April 1978. **Order #7580-8.**

Phillips

CARDIOVASCULAR THERAPY

A Systematic Approach, Vol. 1—**Circulation**

The first of a two-volume set, this is a current highly practical guide to the treatment of common cardiovascular diseases. It covers disorders of circulation, such as hypertension, shock, angina, myocardial infarction, and peripheral arterial and venous diseases. Practical intervention against the various risk factors in atherogenesis are discussed in detail. Volume II, which is in preparation, will focus on diseases of the myocardium, pericardium, valves, and rhythms. Unique features of both volumes include organization by disease, with step-by-step condition management, and special management considerations for pediatric, geriatric, pregnant, and surgical patients.

By **Raymond E. Phillips**, MD, FACP, Senior Attending Physician, Phelps Memorial Hospital, North Tarrytown, NY; Clinical Asst. Prof. in Medicine, New York Medical College, Valhalla, NY. 762 pp. Illustd. $36.00. August 1979. **Order #7216-7.** Vol. II in preparation.

Conn

CURRENT THERAPY 1980

The most widely accepted source of treatment advice—Conn, always new, always reliable. The new 1980 edition offers more clinically useable data than ever before. Completely revised by over 335 leading authorities, it provides 280 articles on the most up-to-date proven treatment methods available. Just look at the listing below:

Highlights of the 1980 Edition

Echinococcosis • malaria • epidemic influenza • bacterial meningitis • infectious mononucleosis • childhood tuberculosis • chronic bronchitis and emphysema • pulmonary embolism • congenital heart disease • tachycardia • varicose veins • hemophilia • lupus • aplastic anemia • acute adult leukemia • untoward reactions to blood transfusions • the malabsorption syndrome • ulcerative colitis • obesity • hyper- and hypoparathyroidism • insect stings • asthma • contact dermatitis • drug eruptions • trauma of the urogenitary system • the venereal diseases • epilepsy • headache • acute head injuries to the adult • juvenile rheumatoid arthritis • dysmenorrhea • hemorrhage in late pregnancy • uterine cancer • alcoholism • burns • and much more!

Order your **Conn** today. Review it for 30 days. If not fully satisfied, write "cancel" across the invoice, return it, and owe nothing.

Edited by **Howard F. Conn**, MD. About 1008 pp. Illustd. $29.50. Ready February 1980. **Order #2708-0.**

AM. JL. CARD 1/80

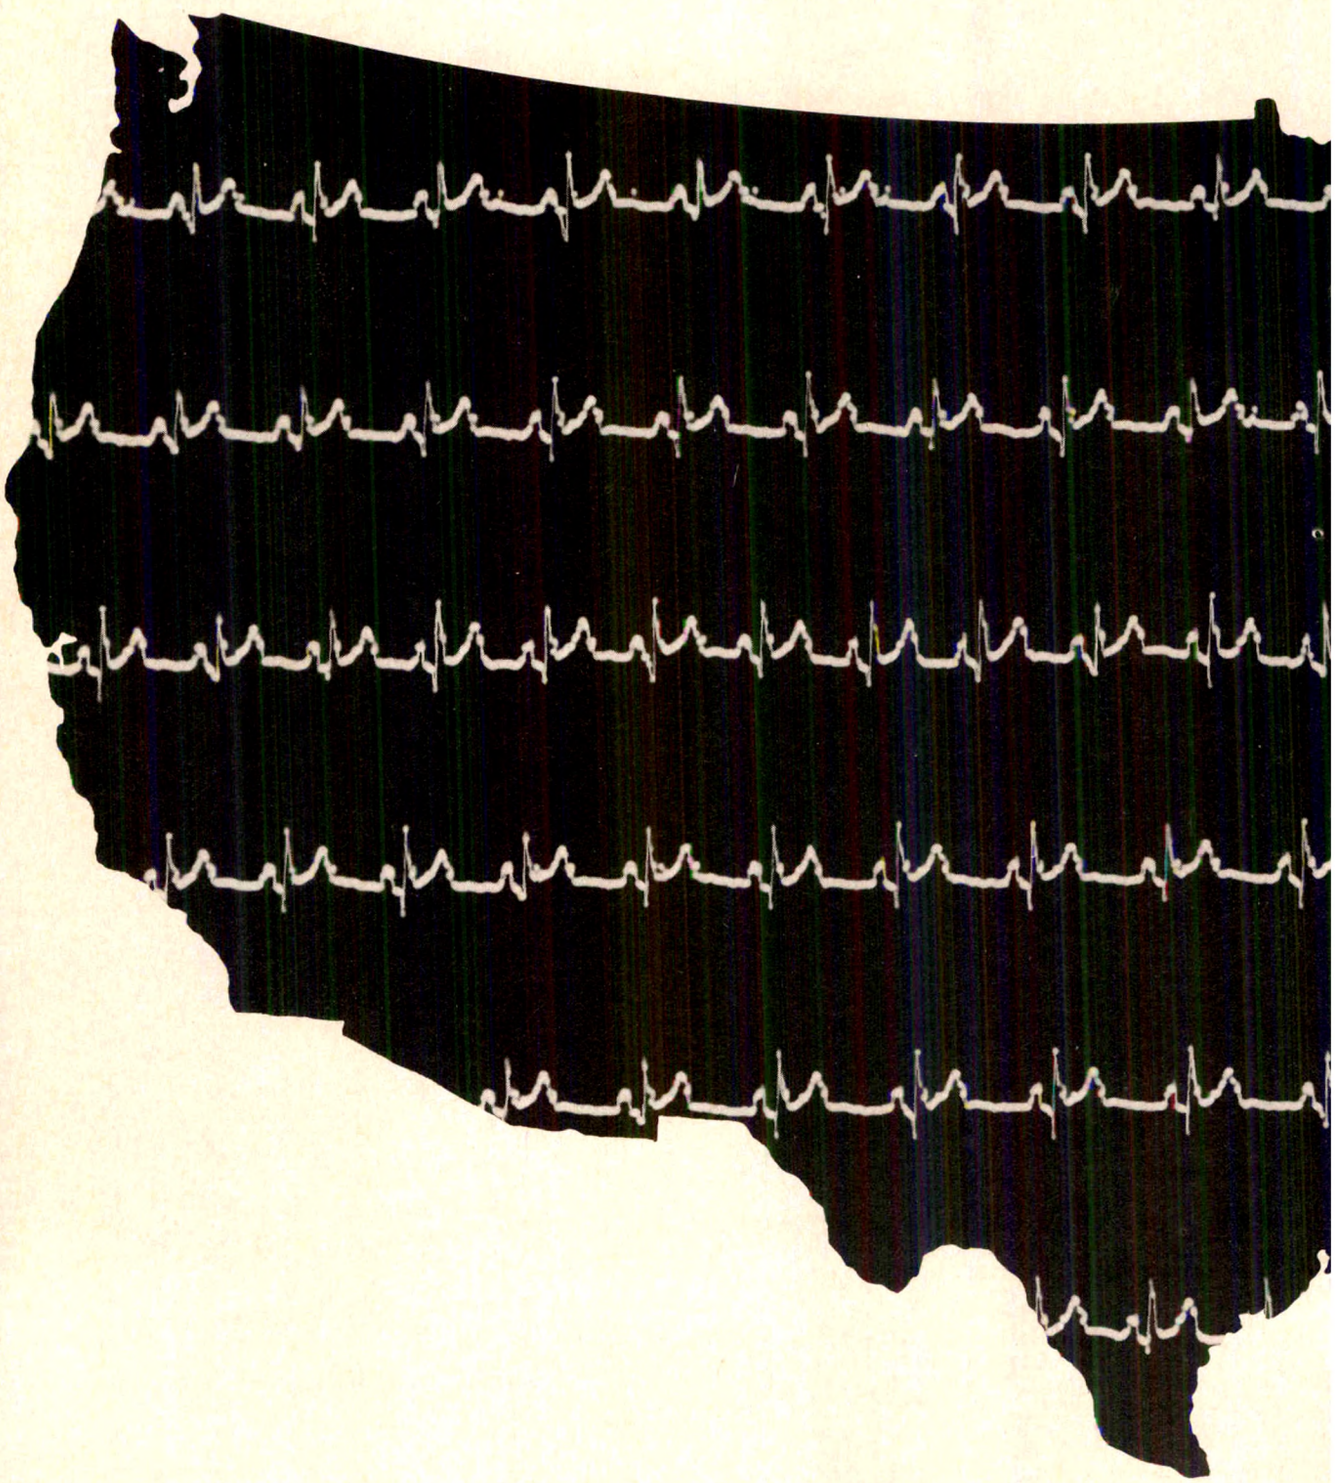
Our long-term ECG reports are delivered nationwide every day, seven days a week, thousands per month.

And for a good reason.

Accuracy.

We honestly believe that no other company – whether offering equipment, reports, or both – can deliver as accurate a long-term ECG (Holter) report. Enough physicians have recognized this to make us – in six short years – the largest reporting service in the country. We've done it with advanced equipment, dedicated people, and proprietary techniques.

Quality control starts with the crystal controlled timing track on our uniquely accurate FM two-lead recorder. It ends with a review of every

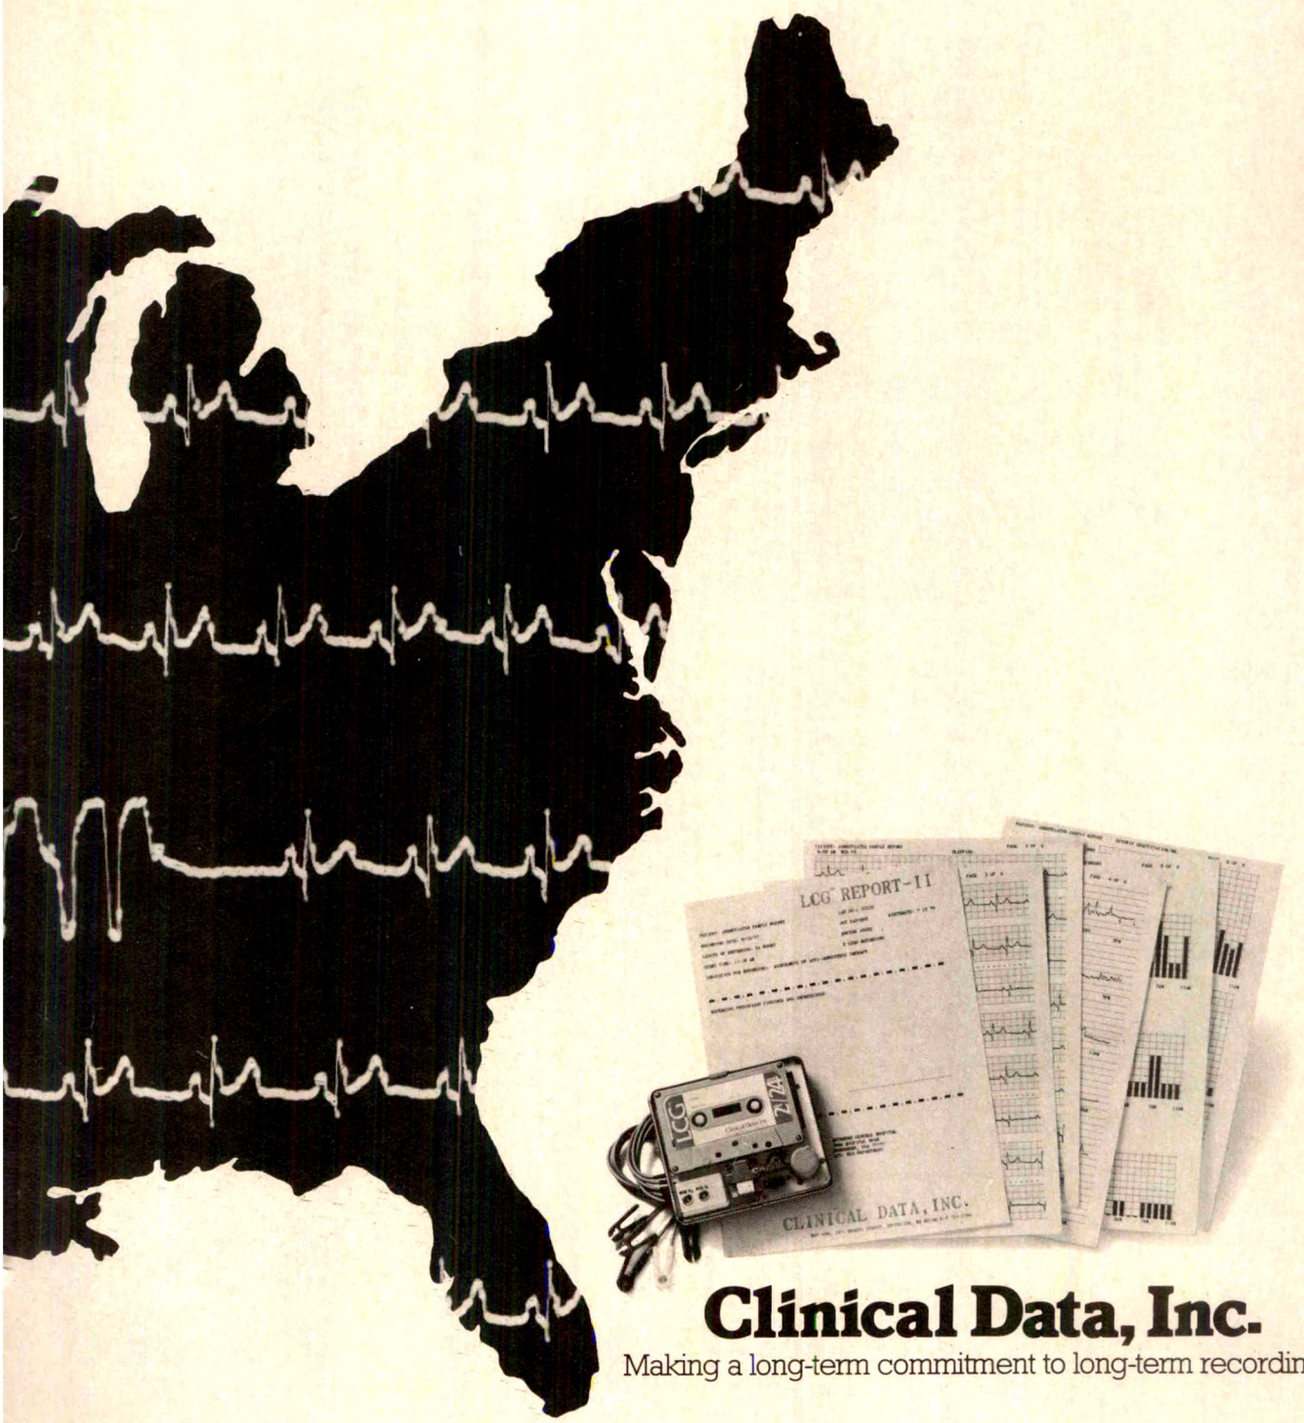


report by a CCU-trained nurse.

In between is our largest contribution to accuracy in long-term ECG reporting – the Stein/Peterson™ examination of data in stationary display. Not a fleeting automated technique, but a sequence of fixed, two-minute ECG segments of the entire 24-hour recording, studied by trained examiners. The pace is set by the examiner, not the computer. We believe people are better than computers at defining significant waveforms.

And we regularly examine our examiner's performance. We regularly examine our recorder's performance. We regularly examine our whole operation, looking for ways to improve it, for which we have a full time staff of medically trained professionals, computer engineers and customer relations people . . . over 110 at this time.

So delivering to you an accurate long-term ECG report is the result of many people commited to quality. And we deliver coast to coast, to many cities within 24 hours. Call us toll free and get the rest of the story: 800-225-9180. Or write for complete information and a sample report: 1371 Beacon Street, Brookline, Mass. 02146



Clinical Data, Inc.

Making a long-term commitment to long-term recording.

Just what the doctor ordered.

Or is it?

We're asking every physician who prescribes Lasix® (furosemide) tablets to show patients how to identify them. If it doesn't say Hoechst it isn't Lasix. Make sure your patient checks for the name "Hoechst" on the tablet.

For over 12 years, Lasix® tablets, manufactured in the U.S. exclusively by Hoechst-Roussel Pharmaceuticals Inc., have been prescribed for millions of patients. It is today one of the most widely prescribed drugs in the world and, clearly, one of the most respected. In fact, it can be characterized as the *diuretic most likely to succeed in all degrees of cardiac edema.*

Furosemide is a unique agent, potent in an unusually wide range of dosage strengths. *But it is also inherently insoluble.* And that's why the manufacture and quality control of this agent are but two of several critical factors in its effectiveness. For it has been shown that drug solubility can alter absorption and thus can seriously affect bioavailability.

And it was apparently this type of problem that prompted the FDA to alert patients that certain unlawfully marketed substitute versions of furosemide "may be ineffective and therefore harmful to patients who need the drug."[1]

Lasix® tablets, on the other hand, have a record of safety and efficacy that is exemplary—a record firmly established in almost 6,000 published papers. Since its introduction, 7.8 billion Lasix® tablets have been manufactured—without a product recall by the Government for any reason. Moreover, stability studies demonstrate that Lasix® tablets remain unimpaired in potency over a five-year period.†

All this is made possible by the thoroughness, experience, integrity and worldwide resources of the Lasix® innovator, Hoechst, the name behind the great clinical success of the product.

So to be sure of consistent performance, tablet after tablet, specify Lasix® and tell patients to double-check that the furosemide they receive is dispensed as Lasix®...available in a wide selection of dosage forms and strengths, including the only oral solution form of the drug.

Lasix®—one less variable in the treatment of cardiac edema.

(furosemide)

Because there's no substitute for quality

asix® (furosemide)

brief summary of the Prescribing Information for Lasix urosemide). Tablets 20, 40 and 80 mg

/ARNING: Lasix (furosemide) is a potent diuretic which, if iven in excessive amounts, can lead to a profound diuresis ith water and electrolyte depletion. Therefore, careful med- al supervision is required, and dose and dose schedule ave to be adjusted to the individual patient's needs.

NDICATIONS: Edema associated with congestive heart failure, rrhosis of the liver, and renal disease, including the nephrotic yndrome. Hypertension when used alone or in combination ith other antihypertensive drugs; patients not adequately con- olled with thiazides also probably will not be adequately con- olled with furosemide alone.

ONTRAINDICATIONS: Because animal reproductive studies ave shown that furosemide may cause fetal abnormalities, ie drug is contraindicated in women of childbearing poten- al. Anuria. History of hypersensitivity to the compound.

/ARNINGS: Excessive diuresis may result in dehydration and duction in blood volume, with circulatory collapse and with ie possibility of vascular thrombosis and embolism, particu- rly in elderly patients. Excessive loss of potassium in patients ceiving digitalis glycosides may precipitate digitalis toxicity. xercise care in patients receiving potassium-depleting eroids. Perform frequent serum electrolyte, CO_2, and BUN de- rminations during first few months of therapy and periodically ereafter, and correct abnormalities or temporarily withdraw e drug. Initial therapy of patients with hepatic cirrhosis and scites is best carried out in the hospital. Closely observe cir- otic patients for sudden fluid and electrolyte imbalances that ay precipitate hepatic coma. Supplemental potassium loride and, if required, an aldosterone antagonist are helpful preventing hypokalemia and metabolic alkalosis. Discon- nue furosemide if increasing azotemia and oliguria occur dur- g treatment of severe, progressive renal disease. Observe atients regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Patients with known sul- namide sensitivity may show allergic reactions. Furosemide ay potentiate the therapeutic effect of other antihypertensive gents. Potentiation occurs with ganglionic or peripheral ad- nergic blocking drugs. Exacerbation or activation of systemic upus erythematosus may occur. Furosemide appears in breast ilk. If use of the drug is essential, the patient should stop ursing. Cases of tinnitus and reversible hearing impairment ave been reported.

here have also been some reports of cases in which irrevers- ble hearing impairment occurred. Usually ototoxicity has been eported when furosemide was injected rapidly in patients with evere impairment of renal function at doses exceeding several mes the usual recommended dose and in whom other drugs nown to be ototoxic were given. If the physician elects to use igh-dose parenteral therapy in patients with severely impaired enal function, controlled intravenous infusion is advisable. For adults, an infusion rate not exceeding 4 mg furosemide er minute has been used.)

RECAUTIONS: As with any effective diuretic, electrolyte deple- on may occur, especially in patients receiving higher doses nd unrestricted salt intake. Patients receiving furosemide hould be observed for clinical signs of fluid or electrolyte mbalance, namely, hyponatremia, hypochloremic alkalosis, nd hypokalemia. Serum and urine electrolyte determinations e particularly important when the patient is vomiting exces- vely or receiving parenteral fluids. Medication such as digi- lis may also influence serum electrolytes. Hypokalemia may evelop with furosemide as with any other potent diuretic, specially with brisk diuresis, when cirrhosis is present, or uring concomitant use of corticosteroids or ACTH. Interference ith adequate oral electrolyte intake will also contribute to ypokalemia. Digitalis may exaggerate metabolic effects of ypokalemia, especially with reference to myocardial activity. symptomatic hyperuricemia can occur and gout may rarely be recipitated. Increases in blood glucose and alterations in glu- ose tolerance tests with abnormalities of the fasting and two- our postprandial sugar have been observed, and rare cases of recipitation of diabetes mellitus have been reported. Furose- ide may lower serum calcium levels, and rare cases of tetany ave been reported. Periodic serum calcium levels should be btained. Reversible elevations of BUN may be seen. These ave been observed in association with dehydration, which hould be avoided, particularly in patients with renal insuffi- iency. Patients receiving high doses of salicylates in conjunc- on with furosemide may experience salicylate toxicity at lower oses because of competitive renal excretory sites. Furosemide as a tendency to antagonize the effects of tubocurarine and ay potentiate the action of succinylcholine. Lithium generally hould not be given with diuretics because they reduce its renal earance and add a high risk of lithium toxicity. Diuretics such s furosemide may enhance the nephrotoxicity of cephaloridine herefore, furosemide and cephaloridine should not be ad- inistered simultaneously. Furosemide may decrease arterial sponsiveness to norepinephrine. This diminution is not suffi- ent to preclude effectiveness of the pressor agent for therapeu- use.

has been reported in the literature that coadministration of domethacin may reduce the natriuretic and antihypertensive fects of Lasix (furosemide) in some patients. This effect has een attributed to inhibition of prostaglandin synthesis by in- omethacin. Indomethacin may also affect plasma renin levels nd aldosterone excretion; this should be borne in mind when renin profile is evaluated in hypertensive patients. Patients ceiving both indomethacin and Lasix (furosemide) should be bserved closely to determine if the desired diuretic and/or ntihypertensive effect of Lasix (furosemide) is achieved.

DVERSE REACTIONS: Anorexia, oral and gastric irritation, ausea, vomiting, cramping, diarrhea, constipation, jaundice nirahepatic jaundice), pancreatitis, dizziness, vertigo, pares- lesias, headache, xanthopsia, blurred vision, tinnitus and earing loss, anemia, leukopenia, agranulocytosis (rare), hrombocytopenia, aplastic anemia (rare), purpura, photosen- itivity, rash, urticaria, necrotizing angiitis (vasculitis, cutane- us vasculitis), exfoliative dermatitis, erythema multiforme, ruritus. Orthostatic hypotension may occur and may be exag- erated by alcohol, barbiturates, or narcotics. Other adverse eactions include hyperglycemia, glycosuria, hyperuricemia, uscle spasm, weakness, restlessness, urinary bladder asm, thrombophlebitis.

How thorough and unbiased is your drug reference?

If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 15th Edition
Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Bonzales, R.Ph., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 15th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. They pass this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Only print material the manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one alphabetic sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main secton as follows:

- GENERAL INDEX of all brand generic names in a-z sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selectin of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

And, our Free Updating Service informs you of changes in specifications and introduces new drugs. You receive them free of charge until the publication of the next (16th) Edition.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

YORKE MEDICAL GROUP, 666 Fifth Avenue, N.Y., N.Y. 10019

Please send me a copy of the all-new 15th Edition of MODERN DRUG ENCYCLOPEDIA and enter my two year free subscription to the Periodic Updating Service. If this new edition is the best drug information reference for practitioners available, I will remit $38.95, plus shipping. Otherwise, I will return it within 30 days and owe nothing.

☐ Check here if enclosing $38.95 now as full payment. Publisher pays shipping. Same return guarantee

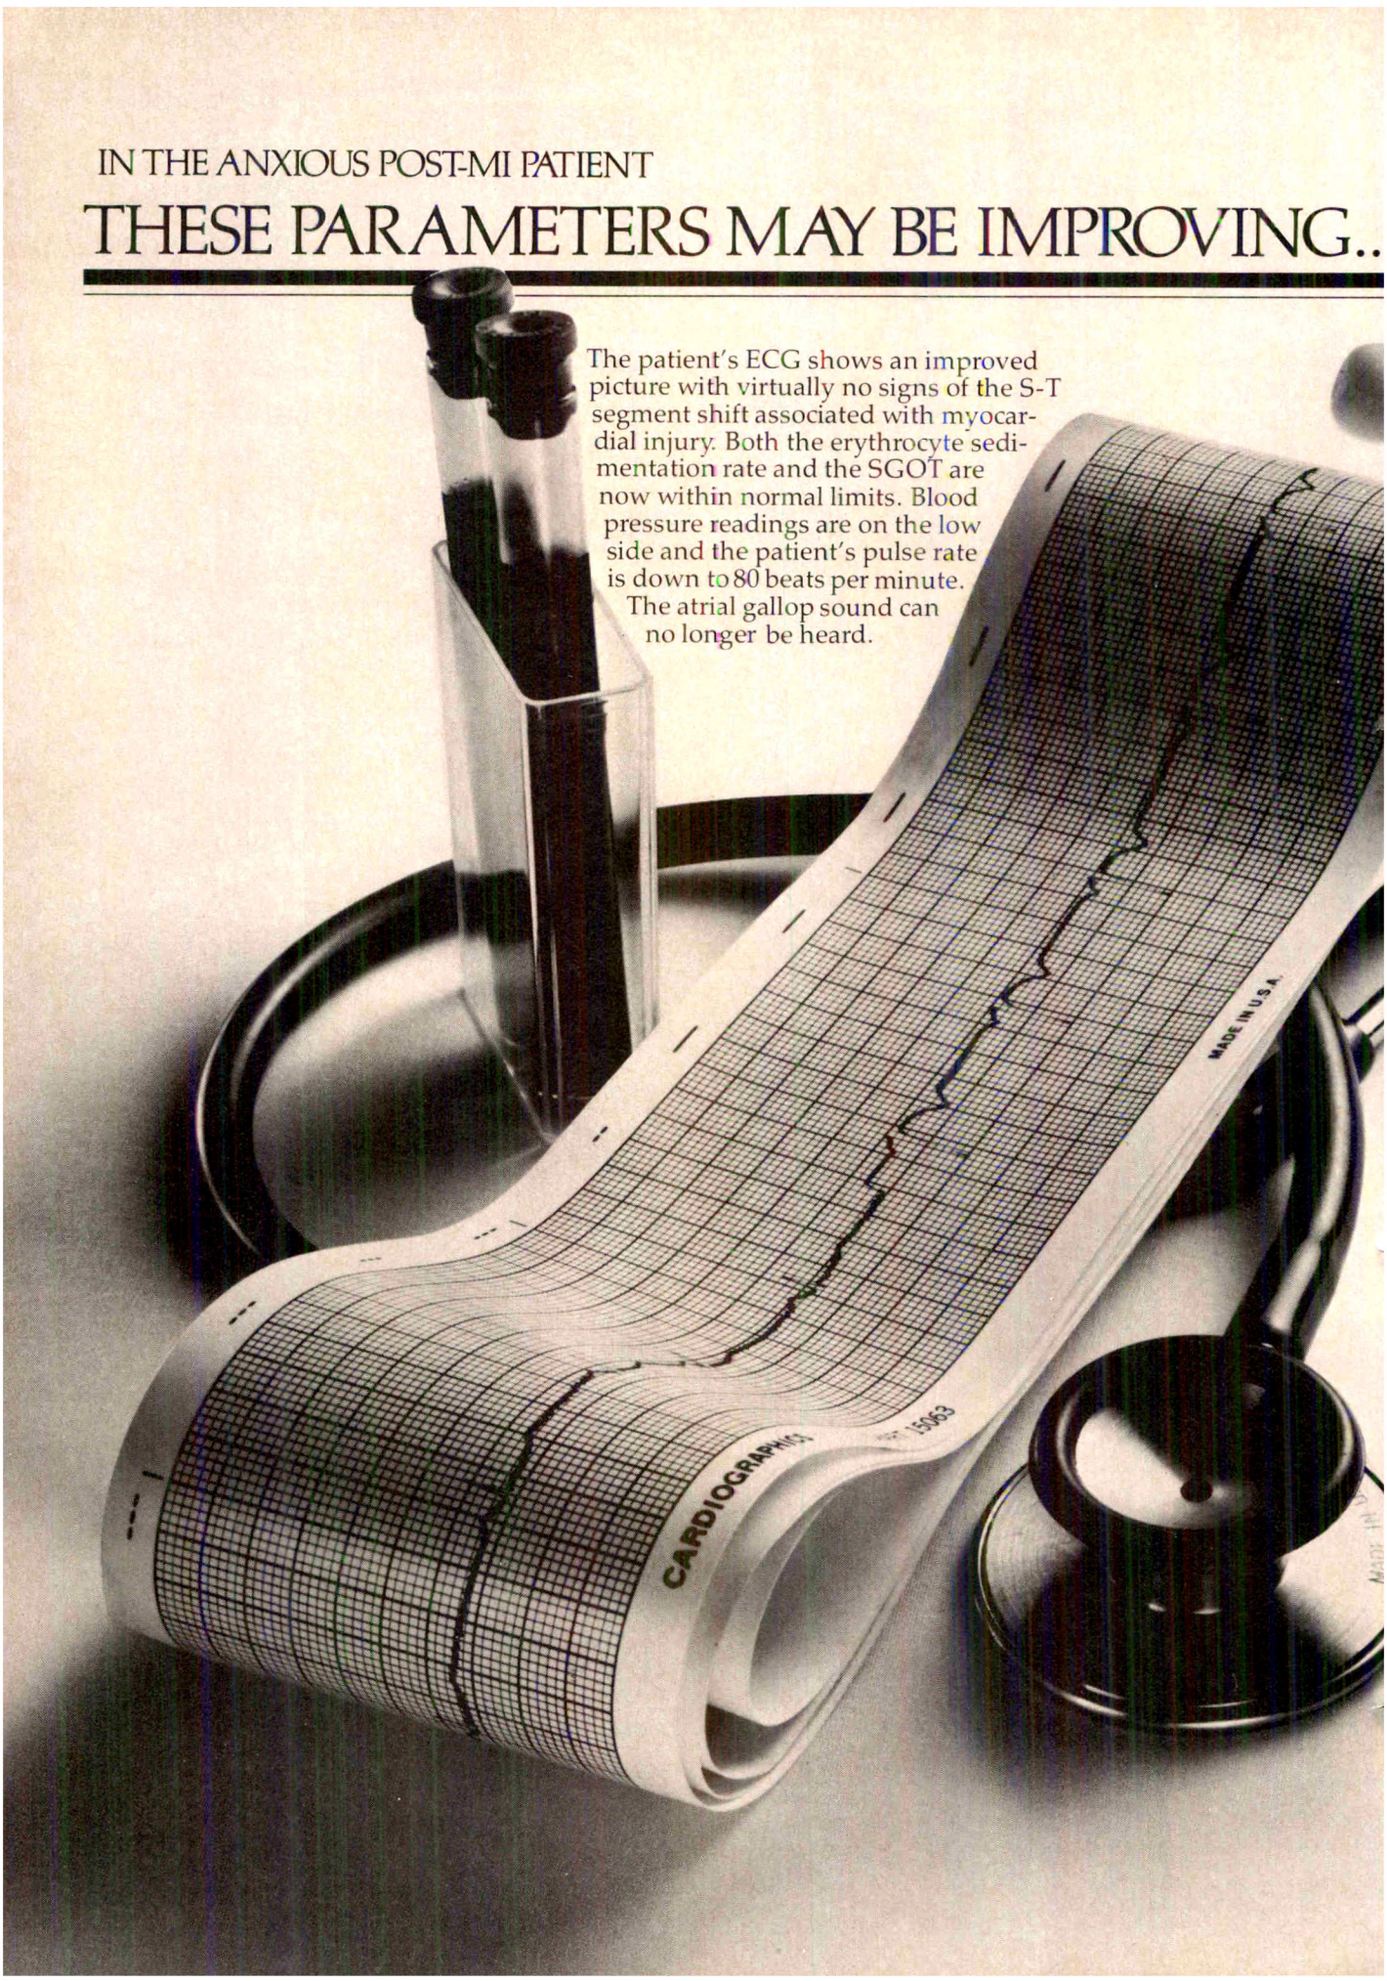
AJC-1/80

IN THE ANXIOUS POST-MI PATIENT

THESE PARAMETERS MAY BE IMPROVING..



The patient's ECG shows an improved picture with virtually no signs of the S-T segment shift associated with myocardial injury. Both the erythrocyte sedimentation rate and the SGOT are now within normal limits. Blood pressure readings are on the low side and the patient's pulse rate is down to 80 beats per minute. The atrial gallop sound can no longer be heard.

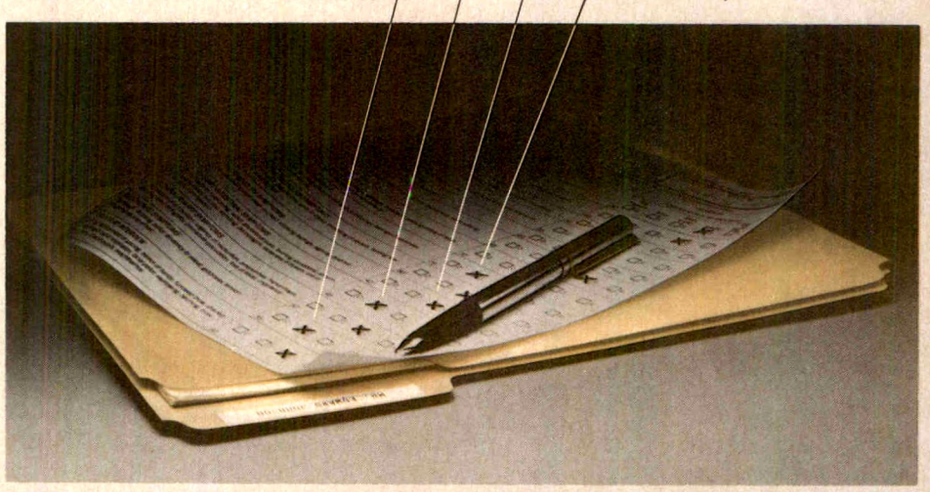
BUT THESE MAY NOT.

You've assured the patient, time and again, that he's making excellent progress, that all signs point to a marked improvement in his condition. He *seems* to understand... and yet, his excessive anxiety and psychic tension continue to pose problems.

For patients like this, adjunctive Valium (diazepam) can be particularly useful. Valium works promptly: patients often feel distinctly calmer in hours, usually report significant symptomatic relief within days. And once calmer and in better control of their emotions, they tend to be more optimistic as well and to enter more willingly into rehabilitative programs.

Valium can also alleviate the anxiety-linked insomnia so often seen in post-MI patients. In most cases, adding an *h.s.* dose of Valium to the usual *t.i.d.* schedule helps relieve "nighttime apprehensions" and encourages sleep. And Valium is used with most classes of primary medications, including cardiac glycosides, anticoagulants, diuretics and vasodilators.

An especially important advantage: Valium (diazepam) is usually well tolerated. Though drowsiness, ataxia and fatigue are encountered with some patients, these and more serious side effects are rarely a problem. Patients who will be taking Valium during their first weeks at home should be cautioned against the simultaneous drinking of alcohol. Periodic reassessment of the patient's need for psychotropic medication is also recommended.



VALIUM® (IV)
diazepam/Roche
2-mg, 5-mg, 10-mg scored tablets

TO REDUCE EXCESSIVE ANXIETY TO MORE MANAGEABLE LEVELS

Before prescribing, please see following page for a summary of product information.

ROCHE

Valium® (diazepam/Roche)

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).

The effectiveness of Valium (diazepam) in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10.

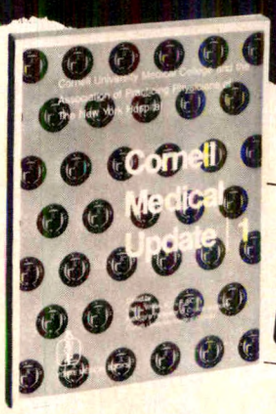
How to Keep Up with the Most Recent Advances in Your Specialty

in the Comfort of Your Home or Office



NOW—in book form—the famous UPDATE YOUR MEDICINE CONFERENCES

CORNELL MEDICAL UPDATE 1

208 PAGES
74 ILLUS.
KIVAR COVER

EDITED BY Lila A. Wallis, MD, FACP

This new book is designed for the busy physician who finds it difficult to keep up with the growing literature in his profession. Up until now the only way this could be done was to attend such conferences as the highly acclaimed Update Your Medicine sponsored by New York Hospital, Cornell Medical Center. These programs were developed to prepare doctors for Recertification despite heavy work loads.

AMA Physician's Recognition Award

CORNELL MEDICAL UPDATE I has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit is included with every copy.

Read it for 30 days—FREE
Use it to check any problems which come up in your practice throughout a full month. Then keep the book only if you want it for permanent reference. Otherwise simply return it and owe nothing. You have nothing to lose and a whole world of valuable life-saving knowledge to gain. Order right now!

The 16 Lectures are Presented in Compact Workbook Style for Quick Reading and Easy Comprehension:

1. Update Your Endocrinology I: Thyroid & Gonad
2. Update Your Endocrinology II: Hypothalamus and Anterior Pituitary
3. Update Your Cardiology
4. Update Your Gastroenterology: Chronic Active Hepatitis
5. Update Your Gastroenterology: GI Hormones
6. Nephrology: Renal Physiology and Diuretic Therapy
7. Recent Advances in Cancer Chemotherapy
8. Compendium of Antineoplastic Agents
9. Update Your Immunology: Hypersensitivity States
10. Update Your Immunology: Immunopharmacology of Asthma
11. Advances in Neurology
12. Update Your Radiology: Angiography of the GI Tract in Management of Acute Arterial Bleeding
13. Update Your Radiology: Sonography of the Abdomen
14. Recent Advances in Diabetes Mellitus and Hypoglycemia
15. Evaluation of the Program by the Reader
16. Evaluation of the Reader—for the AMA Physician's Recognition Award Credits

Yorke Medical Books AJC-1/80

cardiocare

Medtronic... leading the way to man's heart.

Medtronic...a name synonymous with technological advancement in heart care through the years. A name that means superb craftsmanship and superior reliability in applied biomedical engineering today. A name that stands for commitment to excellence in cardiac screening, diagnosis, treatment and rehabilitation.

Medtronic helps you help the heart patient with a broad spectrum of outstanding products and services. Medical Data Systems, a division of Medtronic, specializes in software programs for nuclear cardiology. Cardiocare, another division, provides monitoring and arrhythmia detection services. Kastec Corporation produces prosthetic heart valves.

With the broadest selection of pacing leads, an entire family of accessories, and now, the introduction of the remarkable new Spectrax pacers and programmers, Medtronic continues leading the way to man's heart.

Medtronic®

When the pressure's on, Norton performs!

Choose Norton for reliability and accuracy in all invasive monitoring procedures.
Consider these advantages when using Norton Monitoring/Administration and Extension Lines.

Clear lines and connectors permit instant visual check for air bubbles.

Integral fittings and connectors insure leak-proof seals.

Winged connectors provide non-slip handling, even when hands are wet.

Controlled damping for accurate pressure readings.

Standard luer-lock dimensions are compatible with most fittings and monitoring components.

These Norton efficiencies and safeguards protect you and your patient.

Norton Monitoring/Administration and Extension Lines are ready to perform for you.
Single-patient use reduces possibility of cross-infection.

Color tabs in every monitoring line package insure consistent set-up and component replacement.

Individual Tyvek* package assures product sterility and integrity.

*Registered Trademark E I Du Pont De Nemours & Co. Inc.

Norton offers a variety of lines.
Monitoring/Administration Lines are available in standard .060" ID as well as low volume .040" ID. Proper type of connector and length are available to meet virtually any need.

Special Extension Lines come complete with pre-attached three-way stopcock and allow for maximum flexibility during set-up and monitoring.

When the pressure's on,
order Norton Monitoring/Administration Lines and Extension Sets. Contact your Norton representative or medical products distributor for all the details.

At Norton, we compound raw material, mold, extrude, assemble, package, and distribute. And we're uncompromising when it comes to product integrity.

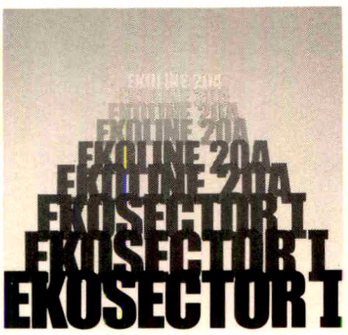
Announcing the SKI M-mode to Real-time Conversion Program.

A unique opportunity for owners of the Ekoline 20A®.



There'll never be a better time to expand your M-mode system to scanning.

Here's what we'll do to help.

We will exchange your Ekoline 20A M-mode system for a new factory assembled and calibrated EkoSector I® two-dimensional scanning system with a full one-year warranty at a price which is bound to match your needs and budget. And to make your procedures easier and faster, you get at no extra charge our M-mode Transducer Kit and 30° High Resolution Probe Head.

Take advantage of this special offer today.

For more details, call toll-free 800-538-1556. In California, call collect 408-732-6000. Or return this coupon.

The Pacekeeper™

For ventricular arrhythmias.
For atrial arrhythmias.
For smooth, trouble-free conversion.
For steady maintenance.

CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

- ☐ Greater GI tolerance than with quinidine sulfate
- ☐ Full quinidine cardiodynamics
- ☐ Convenient b.i.d. or t.i.d. dosage for most patients

CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of a broad range of cardiac arrhythmias (see Brief Summary). After conversion to normal sinus rhythm—whether with CARDIOQUIN Tablets or electroconversion—only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required for maintenance in most cases. The polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*Aviado, D. M., Krantz and Carr's Pharmacologic Principles of Medical Practice, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heart-block; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinicine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 100.

Because ALDORIL® provides benefits day after day...
SPHYGMOMANOMETER
CERTIFIED
mmHg
Copyright © 1979 by Merck & Co., Inc.

many hypertensives have benefited year after year

cardiovascular benefits

cardiac output usually maintained
sodium and fluid retention generally controlled
two highly effective complementary agents

As a fixed combination, ALDORIL is not indicated for initial therapy since hypertension requires therapy titrated to the individual patient. If an available strength of ALDORIL meets the patient's titrated needs, the combination drug may be more convenient in patient management. Therapy should be reevaluated as necessary.

ALDORIL is contraindicated in active hepatic disease; anuria; hypersensitivity to methyldopa or to hydrochlorothiazide or other sulfonamide-derived drugs; if previous methyldopa therapy has been associated with liver disorders. In patients with renal disease, thiazides may precipitate azotemia. Use with caution in patients with severe renal disease or impaired hepatic function.

It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. For more details, see the brief summary of prescribing information.

For a brief summary of prescribing information, please see following page.

practical benefits

- **effects on daily activities usually minimal:** There is less frequent symptomatic postural hypotension with ALDORIL than with many other antihypertensive agents. Exercise hypotension and diurnal blood pressure variations rarely occur.
- **greater dosage convenience:** a b.i.d. regimen is possible for many patients
- **four dosage strengths:** offer the widest range of dosage strengths available in a combination antihypertensive

WARNING

This fixed combination drug is not indicated for initial therapy of hypertension. Hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see **Warnings**); anuria; hypersensitivity to methyldopa or to hydrochlorothiazide or other sulfonamide-derived drugs.

Warnings: METHYLDOPA—**It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions.**

With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood.

At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within the first three weeks of therapy, sometimes with eosinophilia or abnormalities in one or more liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually within the first two to three months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever, abnormalities in liver function tests, or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients.

Rarely, reversible reduction of white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Follow patients carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

HYDROCHLOROTHIAZIDE—Use with caution in severe renal disease. In patients with renal disease, thiazides may precipitate azotemia. Cumulative effects may develop in patients with impaired renal function. Use with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma. May add to or potentiate action of other antihypertensive drugs. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possibility of exacerbation or activation of systemic lupus erythematosus has been reported. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity; read circulars for lithium preparations before use of such concomitant therapy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant requires that anticipated benefits be weighed against possible risks.

Methyldopa and thiazides cross the placental barrier and appear in cord blood.

No unusual adverse reactions have been reported in association with the use of methyldopa during pregnancy. Although no obvious teratogenic effects have been reported, the possibility of fetal injury cannot be excluded.

The hazards of thiazides crossing the placental barrier include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in adults. Methyldopa and thiazides appear in breast milk. Patients taking ALDORIL should not nurse.

Precautions: METHYLDOPA—Should be used with caution in patients with history of previous liver disease or dysfunction (see **Warnings**). May interfere with measurement of urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites. Involuntary choreoathetotic movements have been observed in patients with severe bilateral cerebrovascular disease. If such movements occur, stop the drug. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

HYDROCHLOROTHIAZIDE—Perform periodic determination of serum electrolytes to detect possible electrolyte imbalance. Observe all patients for evidence of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when patient is vomiting excessively or receiving parenteral fluids. Warning signs or symptoms of fluid and electrolyte imbalance include dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting. Hypokalemia may develop, especially with brisk diuresis, in severe cirrhosis, with concomitant corticosteroids or ACTH, after prolonged therapy, or with inadequate oral electrolyte intake. Hypokalemia can sensitize or exaggerate response of heart to toxic effects of digitalis (e.g., increased ventricular irritability). Hypokalemia may be avoided or treated by use of potassium supplements, such as foods with a high potassium content. Although any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease), chloride replacement may be required in metabolic alkalosis. Dilutional hyponatremia may occur in edematous patients in hot weather; appropriate therapy is water restriction, rather than administration of salt, except in rare instances when the hyponatremia is life threatening. In actual salt depletion, appropriate replacement is the therapy of choice.

Hyperuricemia may occur or acute gout may be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged; latent diabetes mellitus may become manifest. Thiazides may increase responsiveness to tubocurarine. Antihypertensive effects of the drug may be enhanced in postsympathectomy patients. May decrease arterial responsiveness to norepinephrine; this diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. If progressive renal impairment becomes evident, consider withholding or discontinuing diuretic therapy. Thiazides may decrease serum PBI levels without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Pathological changes in the parathyroid glands with hypercalcemia and hypophosphatemia have been observed in a few patients on prolonged therapy; thiazides should be discontinued before testing for parathyroid function.

Adverse Reactions: METHYLDOPA—*Central nervous system:* Sedation, headache, asthenia or weakness; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression. *Cardiovascular:* Bradycardia, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.) *Gastrointestinal:* Nausea, vomiting, distention, constipation, flatus, diarrhea, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis. *Hepatic:* Abnormal liver function tests, jaundice, liver disorders. *Hematologic:* Positive Coombs test, hemolytic anemia. Leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells and rheumatoid factor. *Allergic:* Drug-related fever, lupus-like syndrome, myocarditis. *Other:* Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, impotence, decreased libido, dermatologic reactions including eczema and lichenoid eruptions, mild arthralgia, myalgia.

HYDROCHLOROTHIAZIDE—*Gastrointestinal system:* Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis, sialadenitis. *Central nervous system:* Dizziness, vertigo, paresthesias, headache, xanthopsia. *Hematologic:* Leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia, hemolytic anemia. *Cardiovascular:* Orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics). *Hypersensitivity:* Purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), fever, respiratory distress including pneumonitis, anaphylactic reactions. *Other:* Hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, transient blurred vision. Whenever adverse reactions are moderate or severe, thiazide dosage should be reduced or therapy withdrawn.

Note: Tolerance may occur, usually between the second and third month of therapy. Increasing dosage of either component separately or together frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

How Supplied: Tablets ALDORIL®-15, containing 250 mg methyldopa and 15 mg hydrochlorothiazide, bottles of 100 and 1000; Tablets ALDORIL®-25, containing 250 mg methyldopa and 25 mg hydrochlorothiazide, bottles of 100 and 1000; Tablets ALDORIL® D30, containing 500 mg methyldopa and 30 mg hydrochlorothiazide, bottles of 100; Tablets ALDORIL® D50, containing 500 mg methyldopa and 50 mg hydrochlorothiazide, bottles of 100.

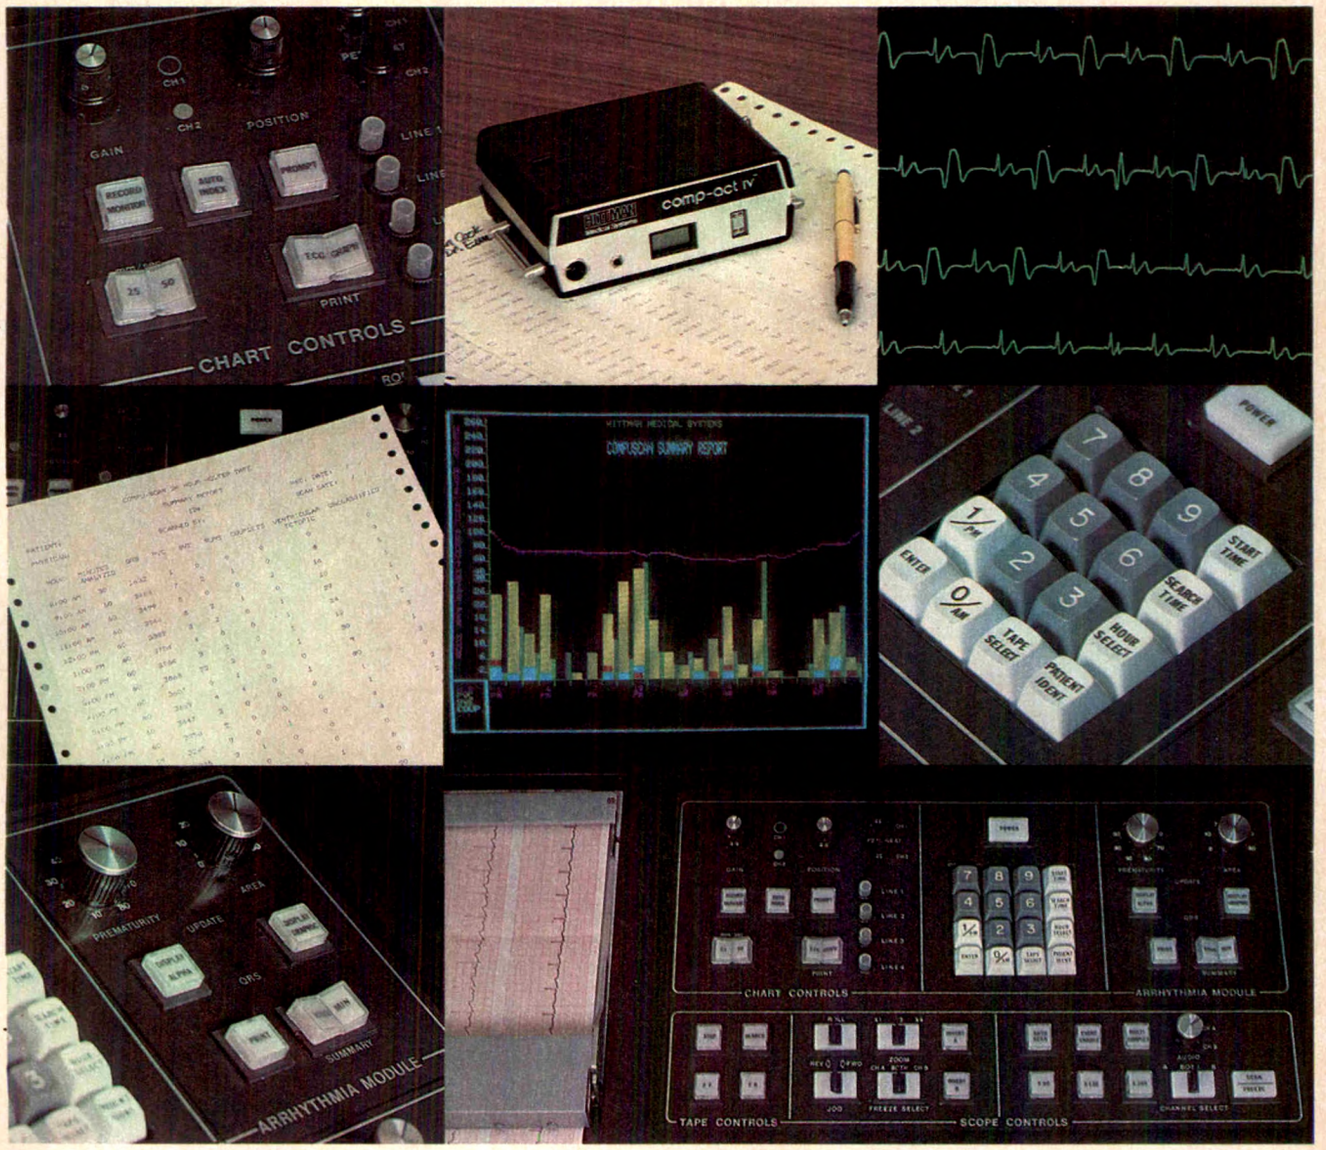
Take A Close Look At Compu-Scan™... The Future in Holter Technology



If you are considering a new Holter System now or in the future, here's why you should take a closer look at Compu-Scan™ —

- ☐ Compu-Scan's new computer based ectopic detection system utilizes an operator determined, continually updated template to accurately measure and categorize every beat
- ☐ Single pass automatic ectopic scan at 240X real time (six minutes)
- ☐ Easy to use control panel designed in cooperation with scanning technicians
- ☐ Computerized arrhythmia detection totally verifiable - automatically
- ☐ 1,440 operator selected times or diary entries programmable
- ☐ Easy to read Alphanumeric and graphic reports presented on the color graphics monitor or graphics printer
- ☐ 256 seconds ECG memory - can page forward or backward through entire 24 hours

- ☐ Scan virtually any manufacturer's tapes, cassette, reel to reel, direct recording or FM
- ☐ Comp-Act IV™, a miniature four channel recorder features FM recording, digitally encoded time on tape and a clock that must be set only once per year
- ☐ Service support - over 40 service centers with 150 technicians nationwide
- ☐ Priced significantly under any system with comparable features

Dear Doctor:

SK&F Co. has traditionally responded to the needs of the patient and the physician. And the introduction of new 'Dyazide' 'PATIENT-PAK' 100's furthers that tradition.

The distinctive appearance of 'PATIENT-PAK' helps lower the risk of misidentification. That's particularly reassuring for elderly patients and those on multiple drug regimens. The bright red safety closure, the special label, and the distinctive red and white capsules all facilitate identification in cases of accidents, overdosage, drug incompatibility or unexpected drug reactions.

New 'PATIENT-PAK' 100's is one more way of helping you help your patients. They'll appreciate the added convenience, the economy, and the simplicity that 'PATIENT-PAK' 100's can bring to the therapeutic regimen.

For your patients' sake, specify 'PATIENT-PAK'.

Sincerely,

William S. Pilling

For patients who need K^+Cl^- one sparkles bright:

KLORVESS® EFFERVESCENT GRANULES offer SPARKLING FAST DISSOLUTION

Each packet (2.8 g) provides 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, and L-lysine monohydrochloride 0.913 g.

- **ready in *seconds* instead of minutes —fast dissolution so unique it's patented***
- **pleasant citrus flavor**
- **each packet delivers 20 mEq of potassium and chloride**
- **easily carried in patient's pocket or purse**
- **can be mixed with water or other liquid for pleasant daily dosage**
- **sugar, sodium, carbohydrate and dye free**

Give your patients the KLORVESS sparkle

Please see brief summary of prescribing information on adjoining page.

Give your patients the KLORVESS® sparkle

Klorvess® Effervescent Granules and Klorvess® (potassium chloride) 10% Liquid

Brief summary of prescribing information

DESCRIPTION: *Klorvess Effervescent Granules:* Each packet (2.8 g) contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g in a sodium-, sugar- and carbohydrate-free effervescent formulation. Dissolution of the packet contents in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

Klorvess (potassium chloride) 10% Liquid: Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

INDICATIONS: For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

CONTRAINDICATIONS: Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

PRECAUTIONS: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements. Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis. High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest. To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve the packet contents of *Klorvess Effervescent Granules* in 3 to 4 ounces of cold water, fruit juice or other liquid or dilute each tablespoonful of *Klorvess (potassium chloride) 10% Liquid* in 3 to 4 ounces of cold water. Both of these solutions should be ingested slowly with or immediately after meals.

ADVERSE REACTIONS: Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest. The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

DOSAGE AND ADMINISTRATION: *Klorvess Effervescent Granules:* Adults—One packet completely dissolved 2 to 4 times daily depending upon the requirements of the patient.

Klorvess (potassium chloride) 10% Liquid: Adults—One tablespoonful (15 ml) completely diluted in cold water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating.

OVERDOSAGE: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

HOW SUPPLIED: *Klorvess Effervescent Granules*—packages of 30 packets (2.8 g each). *Klorvess (potassium chloride) 10% Liquid* (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Effervescent Granules and Liquid are also available in institutional packaging as follows: *Klorvess Effervescent Granules*—packages of 1000 packets; *Klorvess Liquid*—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

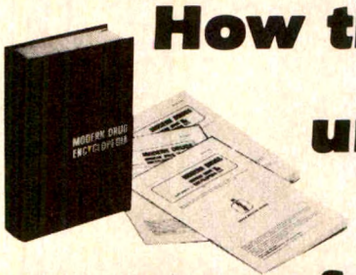
LINCOLN, NEBRASKA 68501



How thorough and unbiased is your drug reference?

If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 15th Edition
Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Bonzales, R.Ph., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 15th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. They pass this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Only print material the manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one alphabetic sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main secton as follows:

- GENERAL INDEX of all brand generic names in a-z sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selectin of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

And, our Free Updating Service informs you of changes in specifications and introduces new drugs. You receive them free of charge until the publication of the next (16th) Edition.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

YORKE MEDICAL GROUP, 666 Fifth Avenue, N.Y., N.Y. 10019
Please send me a copy of the all-new 15th Edition of MODERN DRUG ENCYCLOPEDIA and enter my two year free subscription to the Periodic Updating Service. If this new edition is the best drug information reference for practitioners available, I will remit $38.95, plus shipping. Otherwise, I will return it within 30 days and owe nothing.

☐ Check here if enclosing $38.95 now as full payment. Publisher pays shipping. Same return guarantee
☐ Charge my credit card: ☐ Master Charge ☐ Visa.

AJC-2/80

No matter how close the copy...

wouldn't you rather have the original?

This statuette of Tutankhamun, as the god Horus of Lower Egypt, has been reproduced many times — often in solid gold replicas worth thousands. The original, however, remains priceless.

Lee Boltin/Metropolitan Museum of Art

The original dipyridamole.

During the 17 years that Persantine has been used for long-term therapy of chronic angina pectoris,* physicians have developed an increasing familiarity with this drug. This familiarity is reflected in a steady growth in Persantine use during those years. Clinicians today have extensive experience with dipyridamole, and this experience has been derived from one compound.
Persantine...from Boehringer Ingelheim Ltd.
The original dipyridamole.

Persantine®
(dipyridamole)

*INDICATIONS—Based on a review of this drug by the National Academy of Science-National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.

ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg (2 tablets) three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.
Tablets of 25 mg

CLINICAL STUDIES

197 Left Ventricular Ejection Fraction and First Third Ejection Fraction Early After Acute Myocardial Infarction: Value for Predicting Mortality and Morbidity

ALEXANDER BATTLER, ROBERT SLUTSKY, JOEL KARLINER, VICTOR FROELICHER, WILLIAM ASHBURN AND JOHN ROSS, Jr.

Measurements of total ejection fraction in 102 patients with acute myocardial infarction relatively early after admission failed to show left ventricular dysfunction in one third of patients, whereas the first third ejection fraction obtained with the first pass radionuclide angiographic method appeared to be more highly sensitive for detecting such depressed left ventricular function. The total ejection fraction was reduced in 70 percent and the first third ejection fraction was depressed in 100 percent of the 44 patients with this measurement. A total ejection fraction of less than 0.52 predicted a significantly increased combined morbidity from congestive heart failure and mortality during the 1st year after infarction. A first third ejection fraction of less than 0.17 also predicted increased mortality during that period. It appears that the first third ejection fraction may provide a more sensitive definition of left ventricular function and be a better predictor of 1st year mortality than the total ejection fraction.

203 Regional Left Ventricular Function in Acute Myocardial Infarction: Evaluation With Quantitative Radionuclide Ventriculography

JOSHUA WYNNE, MAUREEN SAYRES, DENIS E. MADDOX, JOHN IDOINE, JOSEPH S. ALPERT, JANE NEILL and B. LEONARD HOLMAN

Using the gated radionuclide ventriculogram to assess the regional performance of infarcted and noninfarcted left ventricular segments after acute transmural myocardial infarction in human subjects, these investigators found that depressed function in apparently noninfarcted left ventricular zones contributes significantly to left ventricular dysfunction, particularly in patients with anterior infarction. Such ventricular dysfunction may occur in left ventricular regions remote from infarcted zones. Prognosis and clinical functional class were related to performance not only in infarcted zones but also in noninfarcted zones as assessed with electrocardiography. Thus, the regional ejection fraction method provides a means of assessing evolutionary changes in regional performance after infarction.

210 Sequential Studies of Left Ventricular Function and Wall Motion After Coronary Arterial Bypass Surgery

LESLIE J. MINTZ, NEIL B. INGELS, Jr., GEORGE T. DAUGHTERS II, EDWARD B. STINSON and EDWIN L. ALDERMAN

In 12 patients studied during the first postoperative year after coronary arterial bypass graft surgery, ejection fraction decreased significantly early postoperatively but recovered to near preoperative values. The data in the early postoperative period were consistent with those observed with an increase in heart rate alone with only a small chronotropic augmentation of the myocardial contractile state. Resting left ventricular performance varied significantly during the 1st postoperative year. Therefore, evaluations made at widely differing times after operation should not be pooled in determining operative results and those made after 2 or 3 months are less variable. Coronary arterial bypass graft surgery can improve wall motion in regions of previous infarction.

217 Combined Right and Left Ventricular Infarction: Pathogenesis and Clinicopathologic Correlations

NORMAN B. RATLIFF and DONALD B. HACKEL

At autopsy 34 percent of 102 consecutive patients who died from myocardial infarction in a coronary care unit were found to have right ventricular infarction associated with transmural infarction of the posterior left ventricle or the interventricular septum, or both. The common pattern of atherosclerosis in this series was severe steno-

An impressive therapeutic performance...

In tune with contemporary antihypertensive thinking

Today antihypertensive therapy has gone beyond the empirical addition of one drug to another. Today's clinician looks for agents that coordinate their action for smoother, more effective control.

A prime example is increasing use of the Apresoline/beta-blocker/diuretic regimen in moderate-to-severe hypertension. Beta blockers, though effective and generally well tolerated, do not lower the high peripheral resistance found in virtually all long-standing hypertension. As a vasodilator, Apresoline deals directly with the problem. It can decrease total peripheral resistance by more than 60%.

Beta blockers, on the other hand, specifically reduce cardiac output, which tends to rise through reflex action with Apresoline therapy, while diuretics counteract the retention of sodium and extracellular fluid.

Harmonizing with the antihypertensive life-style

The Apresoline/beta-blocker/diuretic regimen is relatively free of serious side-effect problems that interfere with daily living.

As the only therapeutic action of Apresoline is its direct arteriolar vasodilator effect, it avoids many distressing side effects. Sexual dysfunction, drowsiness, lethargy, and sedation are virtually unknown. Postural hypotension is rare. These side effects are usually also avoided with a beta blocker.

Accompanying a fall in blood pressure from Apresoline is an increase in cardiac rate and output. Apresoline also maintains or increases renal and cerebral blood flow. As with any antihypertensive agent, use with caution in patients with advanced renal damage. Contraindicated in coronary artery disease.

CIBA

Apresoline® hydrochloride
(hydralazine hydrochloride USP)

TABLETS

INDICATIONS

Essential hypertension, alone or as an adjunct.

CONTRAINDICATIONS

Hypersensitivity to hydralazine; coronary artery disease; and mitral valvular rheumatic heart disease.

WARNINGS

Hydralazine may produce in a few patients a clinical picture simulating systemic lupus erythematosus. In such patients hydralazine should be discontinued unless the benefit-to-risk determination requires continued antihypertensive therapy with this drug. Symptoms and signs usually regress when the drug is discontinued but residua have been detected many years later. Long-term treatment with steroids may be necessary.

Complete blood counts, L.E. cell preparations, and antinuclear antibody titer determinations are indicated before and periodically during prolonged therapy with hydralazine even though the patient is asymptomatic. These studies are also indicated if the patient develops arthralgia, fever, chest pain, continued malaise or other unexplained signs or symptoms.

A positive antinuclear antibody titer and/or positive L.E. cell reaction requires that the physician carefully weigh the implications of the test results against the benefits to be derived from antihypertensive therapy with hydralazine.

Use MAO inhibitors with caution in patients receiving hydralazine.

When other potent parenteral antihypertensive drugs, such as diazoxide, are used in combination with hydralazine, patients should be continuously observed for several hours for any excessive fall in blood pressure. Profound hypotensive episodes may occur when diazoxide injection and Apresoline (hydralazine hydrochloride) are used concomitantly.

Usage in Pregnancy

Animal studies indicate that hydralazine is teratogenic in mice, possibly in rabbits, and not in rats. Teratogenic effects observed were cleft palate and malformations of facial and cranial bones. Although clinical experience does not include any positive evidence of adverse effects on the human fetus, hydralazine should not be used during pregnancy unless the expected benefit clearly justifies the potential risk to the fetus.

PRECAUTIONS

Myocardial stimulation produced by Apresoline can cause anginal attacks and ECG changes of myocardial ischemia. The drug has been implicated in the production of myocardial infarction. It must, therefore, be used with caution in patients with suspected coronary artery disease.

The "hyperdynamic" circulation caused by Apresoline may accentuate specific cardiovascular inadequacies. An example is that Apresoline may increase pulmonary artery pressure in patients with mitral valvular disease. The drug may reduce the pressor responses to epinephrine. Postural hypotension may result from Apresoline, but is less common than with ganglionic blocking agents. Use with caution in patients with cerebral vascular accidents.

In hypertensive patients with normal kidneys who are treated with Apresoline, there is evidence of increased renal blood flow and a maintenance of glomerular filtration rate. In some instances improved renal function has been noted where control values were below normal prior to Apresoline administration. However, as with any antihypertensive agent, Apresoline should be used with caution in patients with advanced renal damage.

Peripheral neuritis, evidenced by paresthesias, numbness, and tingling, has been observed. Published evidence suggests an antipyridoxine effect and the addition of pyridoxine to the regimen if symptoms develop.

Blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura, have been reported. If such abnormalities develop, discontinue therapy. Periodic blood counts are advised during prolonged therapy.

The Apresoline tablets (10 and 100 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Adverse reactions with Apresoline are usually reversible when dosage is reduced. However, in some cases it may be necessary to discontinue the drug.

Common: Headache; palpitations; anorexia; nausea; vomiting; diarrhea; tachycardia; angina pectoris.

Less frequent: Nasal congestion; flushing; lacrimation; conjunctivitis; peripheral neuritis, evidenced by paresthesias, numbness, and tingling; edema; dizziness; tremors; muscle cramps; psychotic reactions characterized by depression, disorientation, or anxiety; hypersensitivity (including rash, urticaria, pruritus, fever, chills, arthralgia, eosinophilia, and, rarely, hepatitis); constipation; difficulty in micturition; dyspnea; paralytic ileus; lymphadenopathy; splenomegaly; blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura; hypotension; paradoxical pressor response.

DOSAGE AND ADMINISTRATION

Initiate therapy in gradually increasing dosages; adjust according to individual response. Start with 10 mg 4 times daily for the first 2 to 4 days, increase to 25 mg 4 times daily for balance of first week. For second and subsequent weeks, increase dosage to 50 mg 4 times daily. For maintenance, adjust dosage to lowest effective levels.

The incidence of toxic reactions, particularly the L.E. cell syndrome, is high in the group of patients receiving large doses of Apresoline.

In a few resistant patients, up to 300 mg Apresoline daily may be required for a significant antihypertensive effect. In such cases, a lower dosage of Apresoline combined with a thiazide, reserpine, or both may be considered. However, when combining therapy, individual titration is essential to insure the lowest possible therapeutic dose of each drug.

sis or occlusion of the left anterior descending and right coronary arteries. Fatal combined right and left ventricular infarction is associated with an unusually large incidence of acute coronary arterial lesions distributed throughout the coronary arterial tree, but most commonly in the proximal right coronary artery. The majority of the acute coronary arterial lesions were thrombotic, but many intramural hemorrhages within atherosclerotic plaques were also found.

222 Clinical Features of Left Main Equivalent Coronary Disease

JOSEPH D. BABB, RICHARD G. SCHMIDT, THOMAS M. BERARD and JOHN M. FIELD

Although the clinical and hemodynamic data in 70 patients with left main equivalent coronary artery disease did not differ significantly from those in 75 patients with left main coronary stenosis, the patients with left main equivalent lesions amenable to surgical intervention did not share the same natural history and high mortality rates of patients with left main coronary disease. Their natural history more clearly resembled that of the patients with operable two or three vessel disease. These patients are not at high risk for early infarction or death and can be discharged on standard medical therapy to await surgery at a later date.

227 Mechanism of the Repetitive Ventricular Response in Man

H. LEON GREENE, PHILIP R. REID and ALLEN H. SCHAEFFER

These electrophysiologic studies in 30 patients indicate that the repetitive ventricular response (production of two or more ventricular premature complexes in response to a single ventricular pacing stimulus during sinus rhythm or atrial pacing) can be associated with clinically important ventricular arrhythmias and probably represents intraventricular rather than proximal His-Purkinje system reentry. In many patients at least two factors generate ventricular arrhythmias: (1) an initiating event, such as a premature ventricular depolarization, and (2) a substrate on which the initiating event can work to produce a substantial, clinically important arrhythmia. The mechanism of reentry is important to any prognostic value of these electrophysiologic tests because induced proximal His-Purkinje reentry can occur in normal persons.

236 Superior QRS Axis of Ventricular Premature Complexes: An Additional Criterion to Enhance the Sensitivity of Exercise Stress Testing

T. JOSEPH MARDELLI, JOEL MORGANROTH and LEONARD S. DREIFUS

These results demonstrate that the axis of ventricular premature complexes occurring during exercise may yield important information that enhances the sensitivity of exercise testing in symptomatic patients with underlying coronary artery disease, particularly when this criterion is used in patients with a nondiagnostic S-T segment response to exercise. Although ventricular premature complexes with a vertical axis during exercise may occur both in normal persons and in those with coronary artery disease, complexes with an abnormal superior axis appear to be a specific marker for coronary artery disease. In 10 patients with angiographically proved normal coronary arteries the exercise-induced ventricular premature complexes had an axis of $-15°$ to $+110°$ (specificity 100 percent). In the 63 patients with coronary artery disease the presence of an axis of $-30°$ to $-120°$ in such exercise-induced complexes showed a sensitivity of 76 percent.

244 Effects of Exercise Training on Left Ventricular Function in Normal Subjects: A Longitudinal Study by Radionuclide Angiography

STEPHEN K. RERYCH, PETER M. SCHOLZ, DAVID C. SABISTON, Jr. and ROBERT H. JONES

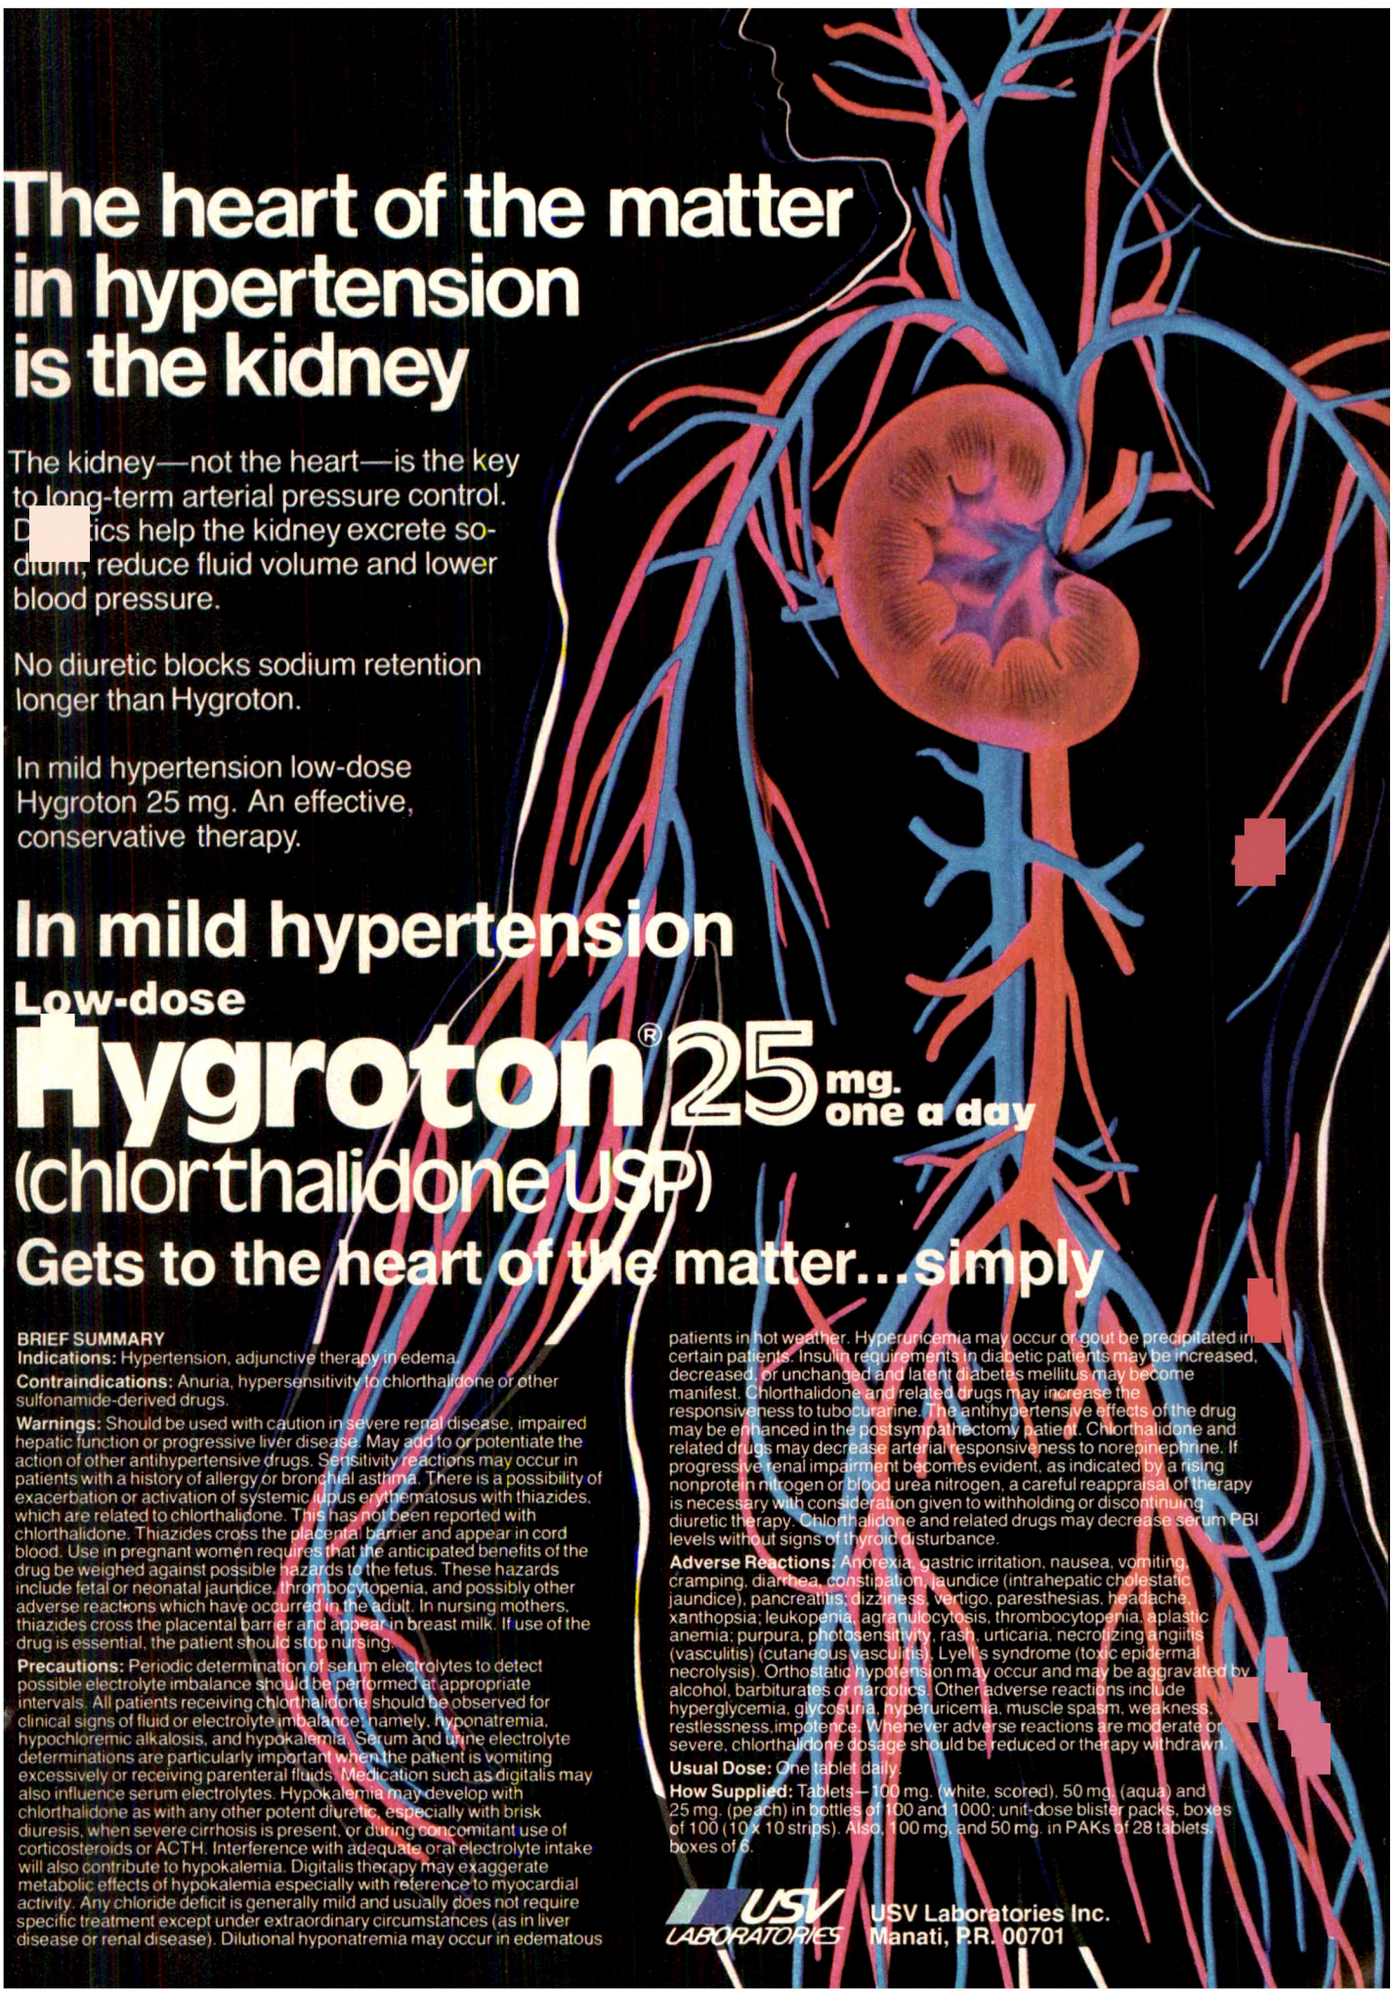
Radionuclide angiographic studies in 18 normal athletes before and after a 6 month period of intensive training for competitive swimming indicate that exercise training appears to enhance cardiac performance primarily by improving the ability of the left ventricle to dilate from rest to exercise and to eject the increased end-diastolic volume of blood at approximately the same or a lower heart rate. Before intensive training, athletes increased cardiac output from rest to exercise primarily by increases in heart rate and stroke volume and by a modest increase in left ventricular ejection fraction and end-diastolic volume. After training, a significant decrease in heart rate and ejection fraction but an increase in end-diastolic volume were noted at rest. Training increases the capacity of the heart to utilize the Frank-Starling mechanism to increase its effectiveness at rest and during periods of maximal cardiac output.

253 Statistical Comparison of M Mode and Two Dimensional Echocardiographic Diagnosis of Flail Mitral Leaflets

GARY S. MINTZ, MORRIS N. KOTLER, WAYNE R. PARRY and BERNARD L. SEGAL

In this prospective study of 45 patients who had surgical therapy for pure mitral insufficiency two dimensional echocardiography proved distinctly superior to M mode echocardiography in the diagnosis of flail mitral valve

Continued on page A21



The heart of the matter in hypertension is the kidney

The kidney—not the heart—is the key to long-term arterial pressure control. Diuretics help the kidney excrete sodium, reduce fluid volume and lower blood pressure.

No diuretic blocks sodium retention longer than Hygroton.

In mild hypertension low-dose Hygroton 25 mg. An effective, conservative therapy.

In mild hypertension

Low-dose

Hygroton® 25 mg. one a day

(chlorthalidone USP)

Gets to the heart of the matter...simply

BRIEF SUMMARY

Indications: Hypertension, adjunctive therapy in edema.

Contraindications: Anuria, hypersensitivity to chlorthalidone or other sulfonamide-derived drugs.

Warnings: Should be used with caution in severe renal disease, impaired hepatic function or progressive liver disease. May add to or potentiate the action of other antihypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. There is a possibility of exacerbation or activation of systemic lupus erythematosus with thiazides, which are related to chlorthalidone. This has not been reported with chlorthalidone. Thiazides cross the placental barrier and appear in cord blood. Use in pregnant women requires that the anticipated benefits of the drug be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier and appear in breast milk. If use of the drug is essential, the patient should stop nursing.

Precautions: Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather. Hyperuricemia may occur or gout be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes mellitus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy. Chlorthalidone and related drugs may decrease serum PBI levels without signs of thyroid disturbance.

Adverse Reactions: Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis; dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn.

Usual Dose: One tablet daily.

How Supplied: Tablets—100 mg. (white, scored), 50 mg. (aqua) and 25 mg. (peach) in bottles of 100 and 1000; unit-dose blister packs, boxes of 100 (10 x 10 strips). Also, 100 mg. and 50 mg. in PAKs of 28 tablets, boxes of 6.

USV LABORATORIES

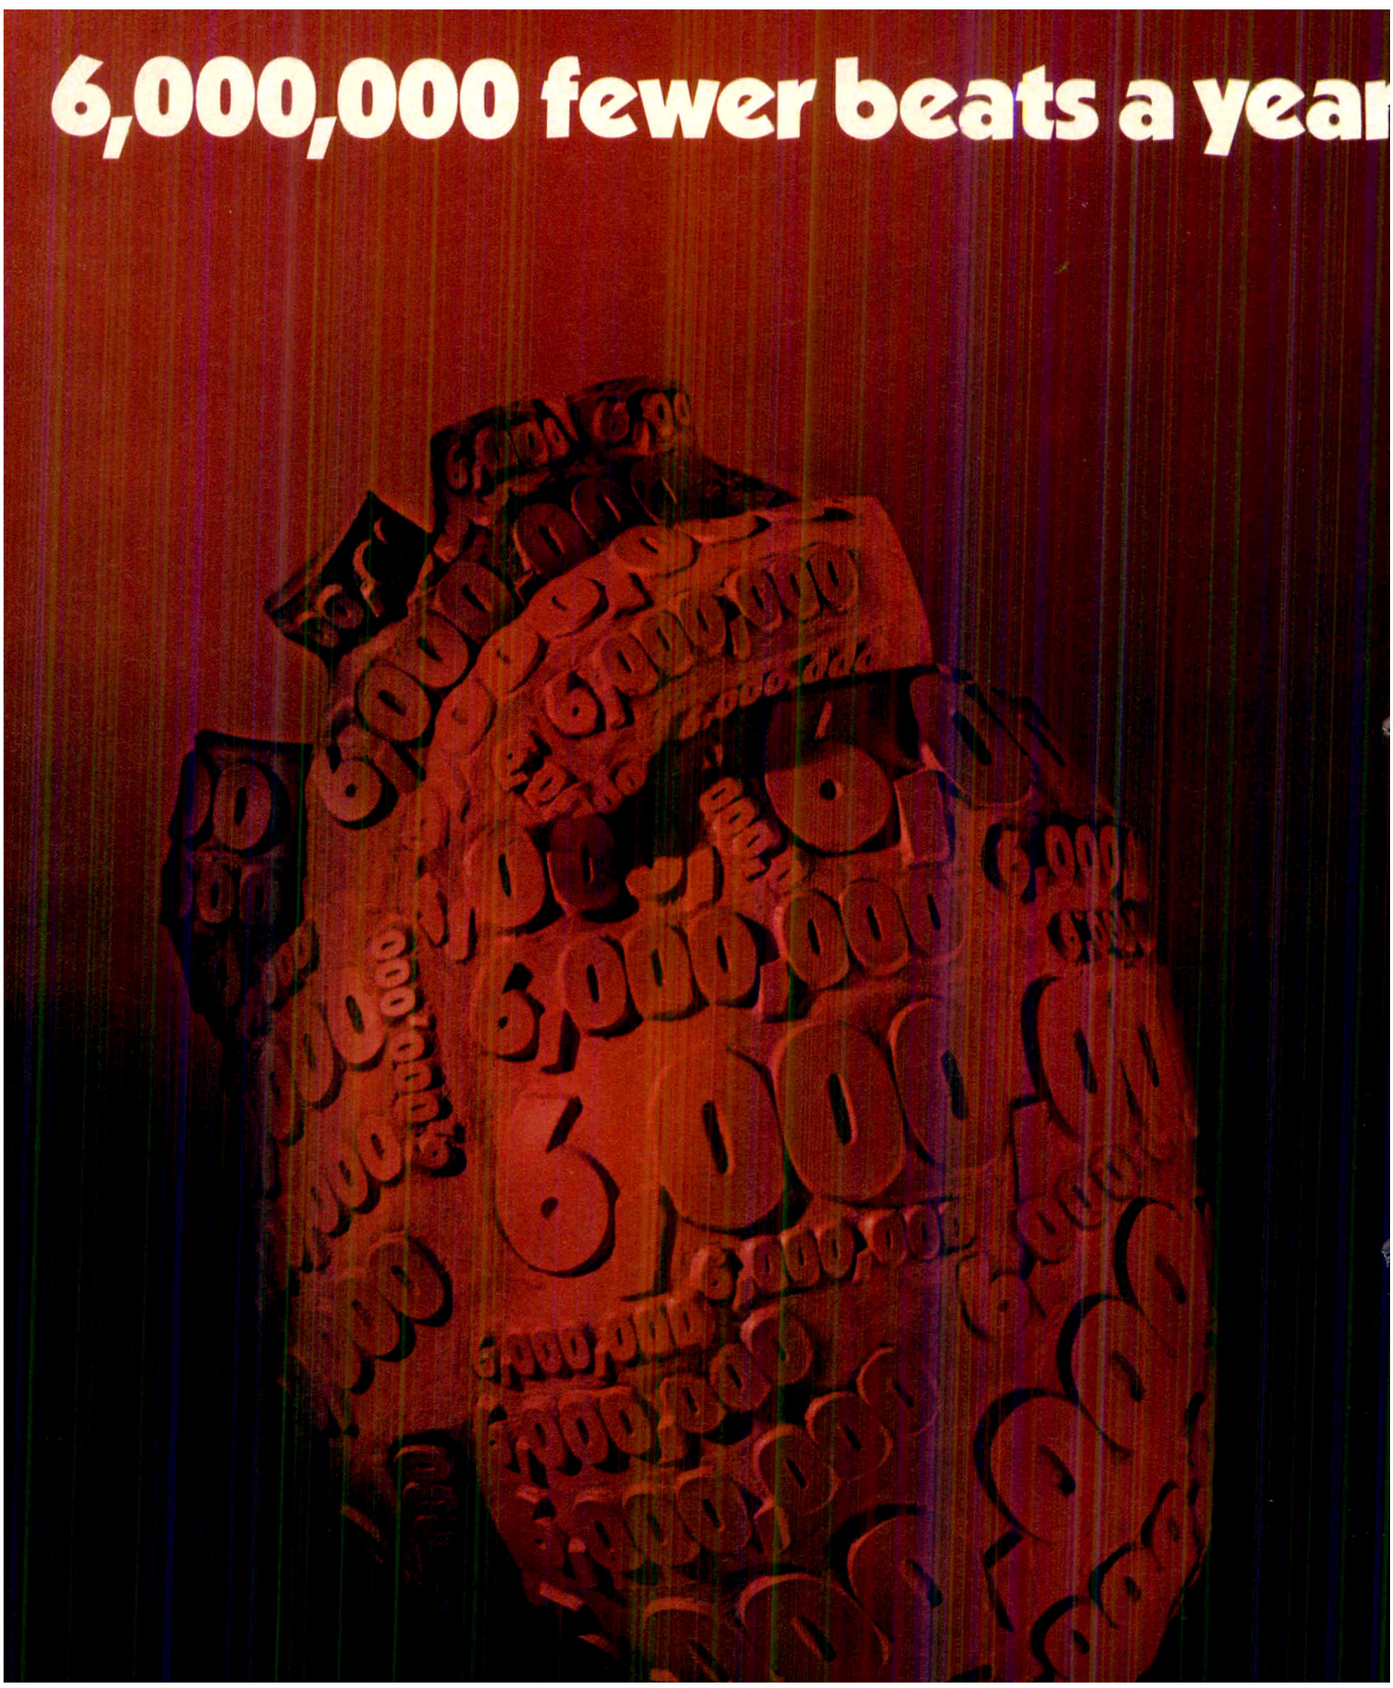
Manati, P.R. 00701



6,000,000 fewer beats a year

Because of the way Inderal® (propranolol HCl) works, the anginal heart doesn't have to work so hard.

Consider the anginal heart at stress: It works harder, faster. Needs more oxygen. Pumps harder, faster still. Strives for more oxygen—with pain. Anginal attack means more nitroglycerin. And that means faster heart rate. The cycle repeats.

Consider Inderal: It reduces heart rate—therapeutically—by some 12 beats a minute.[1-6] 720 fewer beats per hour. Some 6 million fewer beats per year. That means less work for the anginal heart. Less oxygen demand by the myocardium. Fewer anginal attacks. Less need for sublingual nitroglycerin. More tolerance for exercise—and more freedom of action.

Reduction in heart rate is modest: should not be cause for concern.[7] The relatively low dosages required for angina prophylaxis (an average of 160 mg/day) produce few, if any, serious adverse reactions, which in any case are readily recognized and controlled.

With proper patient selection—in the absence of bronchial asthma, sinus bradycardia, or heart block greater than first degree—risk of precipitating cardiac failure is extremely rare. And withdrawal problems may be avoided by reducing dosage gradually—rather than abruptly.*

Consider too: There is also a favorable redistribution of perfusion to the vulnerable subendocardium.[8] And, in patients who may still need nitroglycerin p.r.n., INDERAL will cancel the undesirable increase in heart rate and contractility.

Prescribe INDERAL with confidence. Effective. Reliable. For patients with moderate to severe angina in whom conventional measures have failed.

For full information on Contraindications, Precautions, Adverse Reactions, and Warnings, including avoidance of abrupt withdrawal, please consult the prescribing information on the following page.

BENCHMARK
FOR ANGINA
PROPHYLAXIS

Ayerst

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)

Inderal® BRAND OF
PROPRANOLOL HYDROCHLORIDE
A beta-adrenergic blocking agent

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

ACTIONS

Beta receptor blockade is useful in conditions in which, because of pathologic or functional changes, sympathetic activity is excessive or inappropriate and detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

The proper objective of beta blockade therapy is to decrease adverse sympathetic stimulation but not to the degree that may impair necessary sympathetic support.

Propranolol may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to decreased oxygen requirement.

INDICATION

Angina Pectoris Due to Coronary Atherosclerosis: The initial treatment of angina pectoris involves weight control, rest, cessation of smoking, use of sublingual nitroglycerin, and avoidance of precipitating circumstances. INDERAL is indicated in selected patients with moderate to severe angina pectoris who have not responded to these conventional measures. Propranolol should not be used in patients with angina which occurs only with considerable effort or with infrequent precipitating factors.

INDERAL exerts both favorable and unfavorable effects, the preponderance of which may be beneficial. (See ACTIONS Section.) INDERAL should not be continued unless there is reduced pain or increased work capacity.

Because of the potential for adverse results, treatment should be carefully monitored. The patient should also be reevaluated periodically since the dosage requirement and the need to continue INDERAL may be altered by clinical exacerbations or remissions. (See DOSAGE AND ADMINISTRATION.)

Additional studies of the effects of INDERAL in angina pectoris patients are in progress to better evaluate and define the proper role of INDERAL in this condition.

CONTRAINDICATIONS

INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (i.e., that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by INDERAL's negative inotropic effect. The effects of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, INDERAL therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, e.g., isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (e.g., CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to keep in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. Embryotoxic effects have been seen in animal studies at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura.

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Miscellaneous: reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been conclusively associated with propranolol.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DOSAGE AND ADMINISTRATION

The dosage range for INDERAL is different for each indication.

ORAL

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 10-20 mg three or four times daily, before meals and at bedtime, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg per day. In angina pectoris, the value and safety of dosage exceeding 320 mg per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of several weeks. (See WARNINGS.)

PEDIATRIC DOSAGE

At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

OVERDOSAGE OR EXAGGERATED RESPONSE

IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg); IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY.

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS.

HYPOTENSION—VASOPRESSORS, e.g., LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE).

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE.

HOW SUPPLIED

INDERAL
(propranolol hydrochloride)

TABLETS

No. 461—Each scored tablet contains 10 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 462—Each scored tablet contains 20 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 464—Each scored tablet contains 40 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 468—Each scored tablet contains 80 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

INJECTABLE

No. 3265—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 ml ampuls in boxes of 10.

New York, N.Y. 10017

leaflets. M mode echocardiography had only a sensitivity of 60 percent, a specificity of 53 percent, a predictive accuracy of 63 percent and a predictive value of 50 percent as compared with 96, 84, 89 and 94 percent, respectively, for two dimensional echocardiography. Almost all cases of a flail valve are detectable with a two dimensional study whereas only 60 percent have one or more M mode echocardiographic features. M mode echocardiography appears to detect more readily a flail posterior than a flail anterior leaflet.

260 Complications of the Intraaortic Balloon Counterpulsation Device: Clinical and Morphologic Observations in 45 Necropsy Patients

JEFFREY M. ISNER, STEVEN R. COHEN, RENU VIRMANI, WALTER LAWRINSON and WILLIAM C. ROBERTS

Thirty-six percent of 45 patients who died after insertion of an intraaortic balloon assist device at autopsy had one or more complications related to the use of the device. Only 20 percent of the complications were suspected before death. These included dissection of the aorta or its distal branches, or both (9), arterial perforation (3), arterial thrombi (3), arterial emboli (3), limb ischemia (1) and local wound infection (1). Most complications were consequences of insertion of the device and not consequences of its being in place. The addition of a central lumen to the intraaortic balloon catheter to allow pressure monitoring, the use of aortoiliofemoral angiography or Doppler monitoring, or both, may help avoid complications related to balloon insertion.

EXPERIMENTAL STUDIES

269 Effect of Verapamil on Regional Coronary and Myocardial Perfusion During Acute Coronary Occlusion

PROTÁSIO L. Da LUZ, L. F. MONTEIRO De BARROS, JOÃO JORGE LEITE, FULVIO PILEGGI and LUIZ V. DÉCOURT

S-T segment mapping, retrograde coronary flow and regional coronary resistance studies in 28 dogs subjected to acute coronary occlusion show that verapamil protects the ischemic myocardium by increasing myocardial perfusion and reducing myocardial oxygen consumption. This drug decreased the magnitude of ischemic injury after acute coronary occlusion, reduced regional coronary resistance and increased coronary blood flow to the ischemic zone. Although these results cannot be extrapolated directly to human beings they suggest that this drug may reduce oxygen demand and improve oxygen supply in patients with acute myocardial infarction and that a clinical trial in such subjects is well justified.

276 Altered Coronary Flow Responses to Vasoactive Drugs in the Presence of Coronary Arterial Stenosis in the Dog

WILLIAM P. SANTAMORE and PAUL WALINSKY

These canine studies with intracoronary administered isoproterenol, nitroglycerin, methoxamine and vasopressin indicate that in the presence of severe stenosis the interaction between the stenotic resistance and distal coronary resistance ultimately determines whether a vasoactive agent will increase or decrease coronary blood flow. In the presence of coronary stenosis the normal coronary flow response to a vasoactive drug can be attenuated or even reversed. The observed changes in stenotic resistance may be related to and caused by the changes in coronary pressure. Such an interaction could be an important factor in the therapy of patients with coronary artery disease. For example, in the presence of severe stenosis, distal coronary vasodilatation might paradoxically decrease blood flow by increasing the hemodynamic severity of the stenosed arterial segment.

SPECIAL COMMENTARY

286 Dynamic Coronary Stenosis

K. LANCE GOULD

This special commentary briefly reviews the published data on the dynamic changes of "fixed" arterial stenosis, outlines the basic concepts of fluid dynamics underlying quantitative geometric analyses of stenoses and poses some essential, unresolved questions. The hydraulic mechanisms of coronary arterial stenoses are complex biophysiologic phenomena requiring continuing serious scientific study, especially in relation to the actions of selective coronary vasoactive drugs that produce vasodilation of the proximal stenotic arterial segment and distal arteriolar vasoconstriction. High quality quantitative coronary angiography and high fidelity phasic pressure-flow velocity recordings are needed to sort out the relative importance of the possible mechanisms.

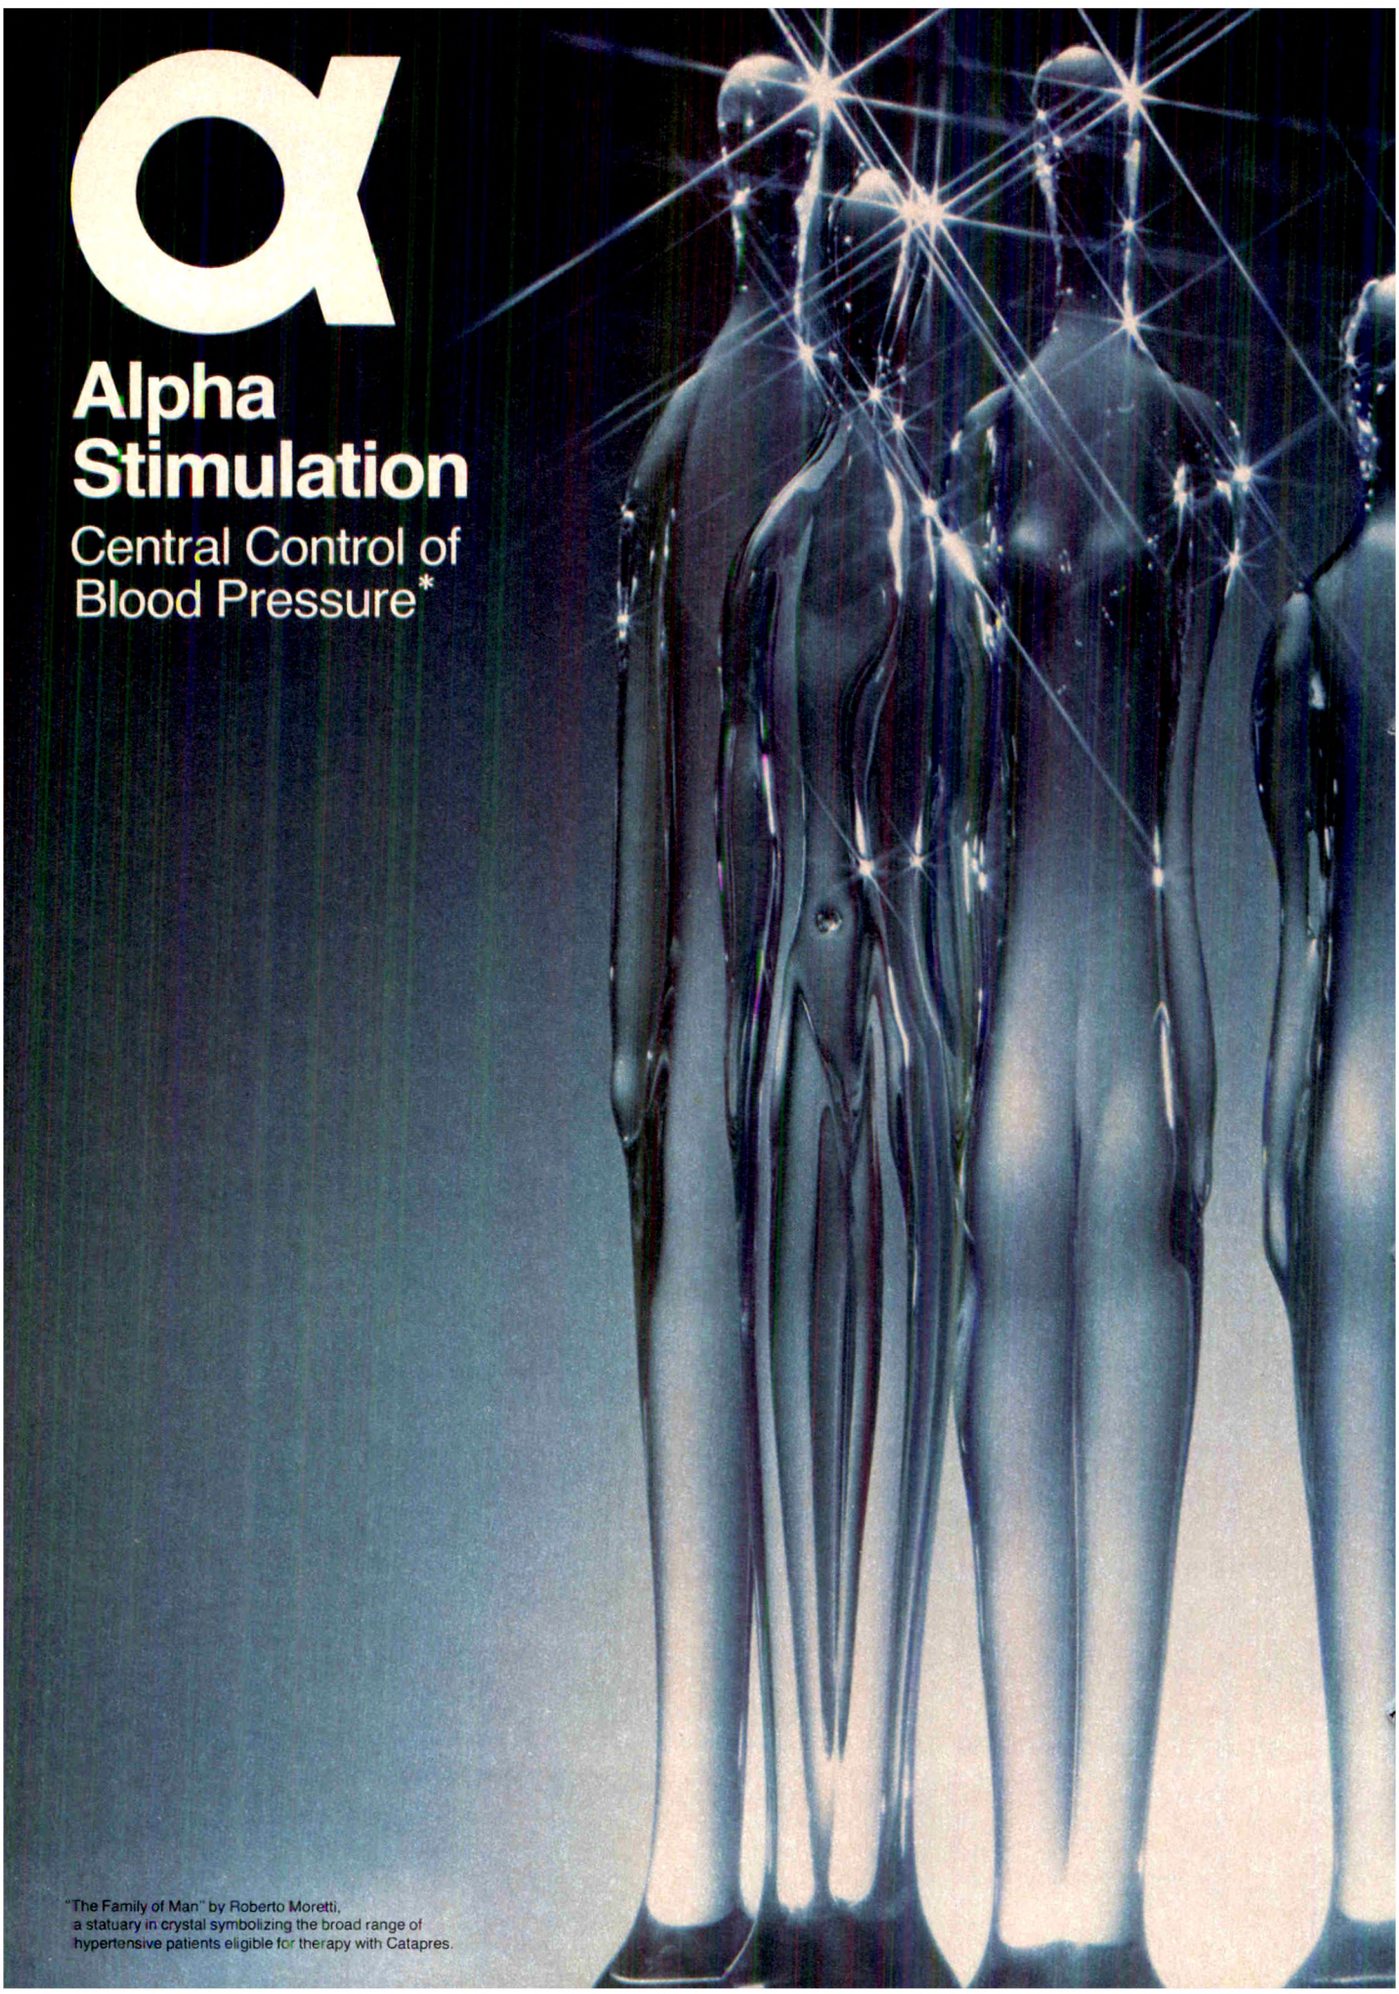
COLLEGE LIBRARY



α
Alpha
Stimulation
Central Control of
Blood Pressure*
"The Family of Man" by Roberto Moretti,
a statuary in crystal symbolizing the broad range of
hypertensive patients eligible for therapy with Catapres.

The Alpha Advantage:

It's for all kinds of hypertensives

- *Unlike beta blockers, Catapres® has no contraindications.*
- *Catapres can be useful even in these patients with:*

Congestive heart failure	Allergic rhinitis
Ventricular hypertrophy	Hepatic disease
Hyperglycemia	Hyperuricemia
Diabetes mellitus	Gouty arthritis
Bronchial asthma	Sulfonamide hypersensitivity

Like any antihypertensive, use with caution in severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

work/play—normal hemodynamic responses to exercise maintained.

love—low incidence of impotence and/or loss of libido: 2.8% in 1,923 patients studied.[1]

cardiac output—tends to return to control values during long-term therapy.

blood flow—preserved in kidney.

No Single Advantage Determines Drug Choice.

Other factors must include:

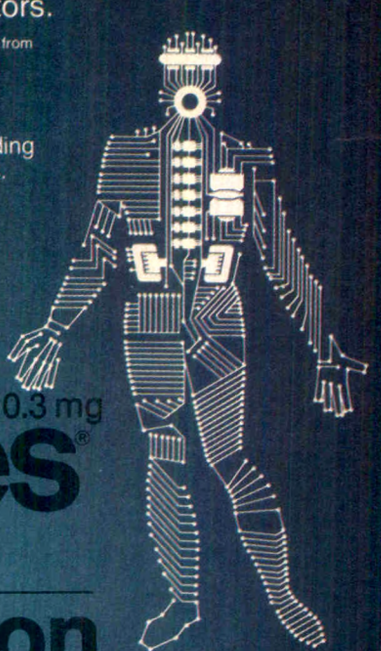
The drug's effectiveness in a given patient, its side effects, warnings, precautions, tolerance, etc. A rational therapeutic choice depends on a careful assessment of all such factors.

*Central alpha-adrenergic stimulation decreases sympathetic outflow from the brain, as shown in animal studies.

1. Data on file at Boehringer Ingelheim Ltd.

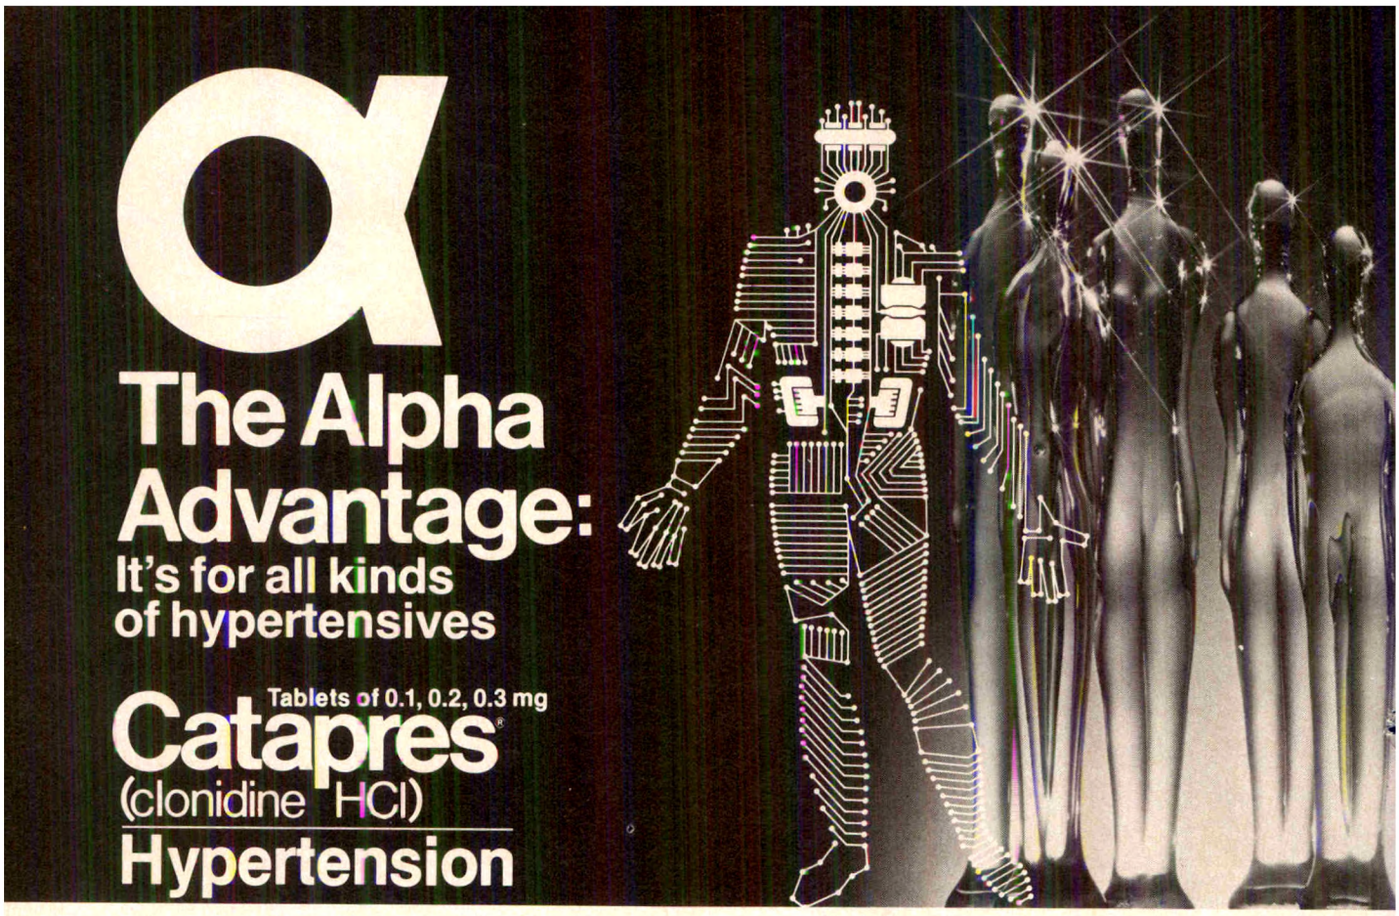
Please see last page for brief summary, including warnings, precautions, and adverse reactions.

Now available in new 0.3 mg tablets



Tablets of 0.1, 0.2, 0.3 mg

Catapres®
(clonidine HCl)
Hypertension



The Alpha Advantage:
It's for all kinds of hypertensives

Tablets of 0.1, 0.2, 0.3 mg

Catapres®
(clonidine HCl)

Hypertension

- No contraindications.
- Effective in all degrees of hypertension. It is mild to moderate in potency.
- Low incidence of depression, impotence, orthostatic hypotension—no fatal hepatotoxicity.
- Preserves kidney blood flow.

Most common side effects are dry mouth, drowsiness, and sedation which generally tend to diminish with time.

The usual starting dose of Catapres is 0.1 mg at brea fast and 0.1 mg at bedtime. Some patients may bene from a starting dose of 0.1 mg at bedtime.

Usual daily dose range—0.2—0.8 mg

Maximum daily dose—2.4 mg
Doses as high as this have rarely been employed.

For optimal results, the dose of Catapres must be adjusted according to the patient's individual blood pressure response.

Catapres®
(clonidine hydrochloride)
Tablets of 0.1, 0.2, 0.3 mg

Indication: The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

Warnings: Tolerance may develop in some patients necessitating a reevaluation of therapy.
Usage in Pregnancy: In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

Precautions: When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 mo longer.

Adverse Reactions: The most common reactions are dry mouth, drowsine sedation. Constipation, dizziness, headache, and fatigue have been rep Generally these effects tend to diminish with continued therapy. The fol reactions have been associated with the drug, some of them rarely. (In instances an exact causal relationship has not been established.) These ir Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormal liver function tests; one report of possible drug-induced hepatitis without j and hyperbilirubinemia in a patient receiving clonidine hydrochloride, thalidone and papaverine hydrochloride. Weight gain, transient elevation of glucose, or serum creatine phosphokinase congestive heart failure, Rayn phenomenon; vivid dreams or nightmares, insomnia, other behavioral cha nervousness, restlessness, anxiety and mental depression. Also rash gioneurotic edema, hives, urticaria, thinning of the hair, pruritus not asso with a rash, impotence, urinary retention, increased sensitivity to alcohol, dr itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecon weakly positive Coombs' test, asymptomatic electrocardiographic abnorm manifested as Wenckebach period or ventricular trigeminy.

Overdosage: Profound hypotension, weakness, somnolence, diminished sent reflexes and vomiting followed the accidental ingestion of Catapres (clo hydrochloride) by several children from 19 months to 5 years of age. lavage and administration of an analeptic and vasopressor led to compl covery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-i intervals usually abolishes all effects of Catapres, (clonidine hydrochloride dosage.

How Supplied: Catapres, brand of clonidine hydrochloride, is available as C (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000 available as 0.3 mg (peach) oval, single-scored tablets in bottles of 100.

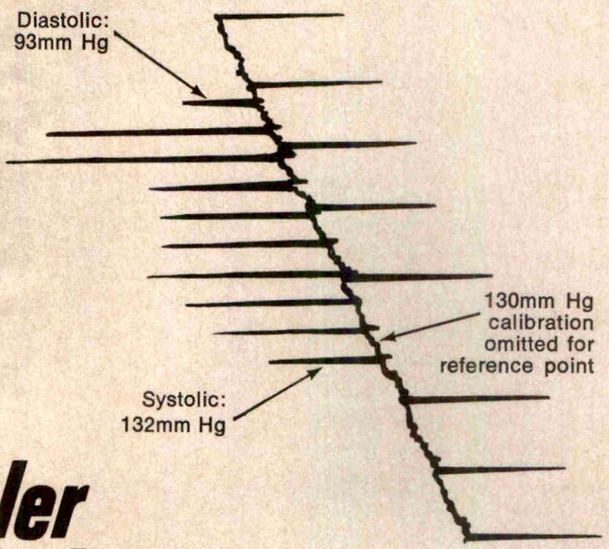
One of as many as 60* blood pressure readings taken throughout the day by an ambulatory patient.



Remler Ambulatory Blood Pressure Recorder...

Light, compact one-piece unit weighs only 25 ounces

The Remler patented Ambulatory Blood Pressure Recorder has been in use for more than ten years by leading physicians and research institutions throughout the world. It is a proven, easy-to-use system and the only available blood pressure device that completely prints out calibrated blood pressure measurements showing all Korotkoff sounds.

This Model M-2000 records blood pressures during the wearer's working or leisure day. Wearing this unobtrusive, light-weight device on a belt, your patient can easily record blood pressure data onto the micro-cassette as many as sixty times daily. This method *totally eliminates bias,* and the pressor effect of an observer's presence.

A further advantage of the Remler system is the substantial savings in cost over manual methods for obtaining a multiple series of blood pressure measurements.

***All Remler Blood Pressure Equipment displays calibrations which are directly traceable to the NATIONAL BUREAU OF STANDARDS.**

METHODS

293 Nongeometric Determination of Left Ventricular Volumes From Equilibrium Blood Pool Scans

GREGORY J. DEHMER, SAMUEL E. LEWIS, L. DAVID HILLIS, DONALD TWIEG, MICHAEL FALKOFF ROBERT W. PARKEY and JAMES T. WILLERSON

Scintigraphic volume measurements calculated from individual frames of a modified 35° left anterior oblique projection showed excellent correlation with angiographic measurements in 22 patients for all volume measurements grouped together as well as for segregated end-diastolic volumes and end-systolic volumes. These and other data indicate that radionuclide techniques, independent of geometric assumptions may be utilized to quantitate left ventricular volumes. This imaging approach requires no additional equipment or time above that already needed for gated blood pool imaging. It is relatively noninvasive, easily repeatable both at rest and during exercise and can be performed in essentially all patients who require clinical cardiovascular evaluation.

301 A New Approach to Visualize the Left Main Coronary Artery Using Apical Cross-Sectional Echocardiography

SATOSHI OGAWA, CHIN C. CHEN, FRANCIS E. HUBBARD, FERREL J. PAULETTO, T. JOSEPH MARDELLI, JOEL MORGANROTH, LEONARD S. DREIFUS, MAKOTO AKAISHI and YOSHIRO NAKAMURA

In these studies of patients undergoing coronary arteriography, apical cross-sectional echocardiography permitted visualization of the left main coronary artery in 27 of 35 consecutive patients and its bifurcation in 12 of the 27. In 26 of the 27 patients cross-sectional echocardiography correctly assessed the patency of the left main coronary artery as judged with coronary angiography. The application of both the short axis and apical cross-sectional echocardiographic approaches to identification of left main coronary arterial obstruction appears to offer a high degree of success in the noninvasive evaluation of patients with suspected coronary artery disease.

PEDIATRIC CARDIOLOGY

305 The Occurrence of Hyperaldosteronism in Infants With Congestive Heart Failure

BARRY G. BAYLEN, GREGORY JOHNSON, REGINALD TSANG, LAXMI SRIVASTAVA and SAMUEL KAPLAN

Serum aldosterone and plasma renin measurements in 20 normal infants and 15 infants with congestive cardiac failure reveal that hyperaldosteronism is an important contributor to fluid and sodium retention in infants with heart failure. Increasing serum aldosterone was related to increasing plasma renin. The administration of an aldosterone antagonist improved diuresis and decreased serum aldosterone. The presence of hyperaldosteronism should be considered in the management of infants with heart failure and signs of fluid retention refractory to treatment. In such infants a trial of aldosterone antagonists such as spironolactone may be useful.

311 Pulmonary Artery Sling

CARL H. GUMBINER, CHARLES H. MULLINS and DAN G. McNAMARA

Six additional cases of pulmonary artery sling (66 have previously been reported) are described along with the clinical features of the condition and therapeutic recommendations. Death from airway obstruction is common before age 6 months in untreated patients. Although vascular surgery provides the only definitive approach to these severely symptomatic children, with critical respiratory obstruction, not all children require operation. Treatment of congestive failure, intracardiac shunts and intrinsic airway disease and respiratory infections may be of critical importance. When surgery is indicated, the outcome may often be influenced by the treatment of associated lesions, including aggressive management of abnormalities of the tracheobronchial tree defined by bronchoscopy.

316 Aberrant Left Pulmonary Artery (Pulmonary Artery Sling): Successful Repair and 24 Year Follow-Up Report

CHARLES D. CAMPBELL, JORGE A. WERNLY, PIPIT CHIEMMONG KOLTIP, DELORES VITULLO and ROBERT L. REPLOGLE

This paper reports a case of anomalous left pulmonary artery arising from the right and coursing behind the trachea and anterior to the esophagus (pulmonary artery sling) which was successfully repaired by ligation of the anomalous vessel and a left pulmonary to main pulmonary arterial anastomosis anterior to the trachea. With re-

Continued on page A30

Predictable angina*

during episodes of emotional stress or physical exertion

SUMMARY OF PRESCRIBING INFORMATION

* **Indications:** Based on a review of this drug by The National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: The chewable dosage form of SORBITRATE is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety.

Precautions: Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: *Individual Dose:* To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an angina attack. CHEWABLE SORBITRATE® (isosorbide dinitrate) may be taken for prompt relief of angina pain three or four times daily. Although the onset and duration of effect of coronary nitrates may vary, following is the generally reported range of these values for CHEWABLE SORBITRATE.

Onset of Effect: Two to five minutes.
Duration of Effect: One to two hours.

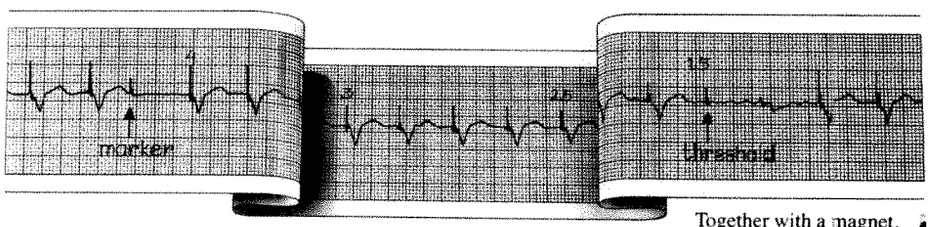
Up to 2 hours of angina protection. At mealtime and any other time of stress.

CHEWABLE SORBITRATE®

(ISOSORBIDE DINITRATE) 5mg. and 10mg.

Vitatron's C1000 and C4000

A new standard in threshold measurement.



Together with a magnet, this is all you need.

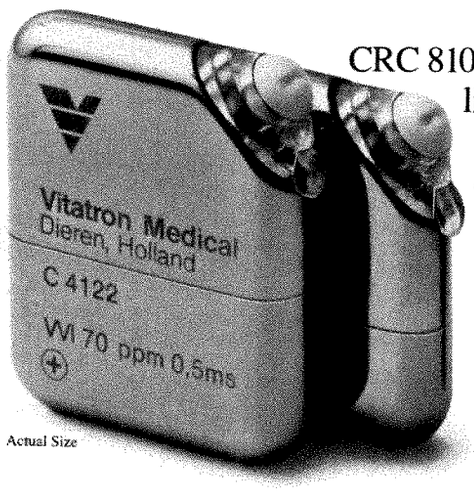
Introducing our C1000 and C4000 pacemakers.

They offer a safer method of *non-invasive* stimulation threshold analysis. One in which all you need is a simple magnet, and a standard ECG recorder.

The magnet starts an output amplitude step-down mode. After completion or at interruption of the step-down cycle, the pacemaker automatically reverts to full output.

How has Vitatron achieved such an important advance? New monolithic integrated injection logic (I^2L) is one reason. Here, all analogue and digital circuitry is contained on a single chip that measures 2.8x2.8 mm.

Overall size of the C1000, incidentally, is mere 50x47x12 mm, with a weight of just 46 grams. The C4000 measures 57x47x12 mm, and weighs 56 grams. Units come in an all-titanium can that's been hermetically sealed by laser welding.



Actual Size

Finally, thanks to our patented dc-dc converter and the CRC 810B lithiode battery, the C1000 has a projected service life of over 9 years*; the C4000, over 15 years.**

Our C1000 and C4000 pacemakers. *Think of them as a new standard in patient safety.*

For specifications write to Vitatron Medical B.V., P.O. Box 76, 6950 AB Dieren, The Netherlands. In the United States: Vitatron Medical Inc., One Gateway Center, Newton, MA 02158.

*Over 6 years service life expected under worst case conditions, 70 ppm, 510 Ohm load, 1.0 millisecond pulse duration; over 9 years, 0.5 ms duration.
**Over 10 years service life expected under worst case conditions, 70 ppm, 510 Ohm load, 1.0 millisecond pulse duration; over 15 years, 0.5 ms duration.

LITHIODE ™
Lithium/Iodine Cell
MODEL 810

finements in exposure and technique of repairing a pulmonary artery sling, the authors believe the present operative mortality rate of 50 percent will decrease and the rate of arterial patency will increase. The severity of associated tracheobronchial and cardiac anomalies will continue to play a major role in the overall survival of these patients.

STUDIES IN HYPERTENSION

321 Hypertension and Propranolol Therapy: Effect on Blood Pressure, Plasma Catecholamines and Platelet Aggregation

NICOLAS D. VLACHAKIS and LOUIS ALEDORT

Plasma catecholamine concentration and platelet aggregation at rest were greater in the 16 hypertensive patients of this study than in the 11 age-matched normotensive healthy subjects. Exercise significantly increased catecholamines and platelet aggregability. The administration of propranolol (240 mg/day) significantly decreased systolic and diastolic blood pressures and platelet aggregation and significantly increased catecholamine concentration at rest but not during exercise. Abrupt withdrawal of propranolol was not associated with any subjective or objective untoward cardiovascular rebound effect or abnormal changes in plasma catecholamines, but platelet aggregability increased significantly.

EPIDEMIOLOGY

326 Blood Pressure and Survival After Myocardial Infarction: The Framingham Study

WILLIAM B. KANNEL, PAUL SORLIE, WILLIAM P. CASTELLI and DANIEL McGEE

Blood pressure and other data obtained biennially from 2,336 men in the Framingham cohort over a 20 year period of follow-up study imply that high blood pressure after myocardial infarction is associated with an increased risk of early death and that a reduction in pressure is of ominous import, suggesting a severely damaged myocardium. Persons with a substantial reduction in blood pressure after a myocardial infarction need investigation for incipient heart failure and may benefit from therapy for failure although they may have no overt symptoms at the time. The blood pressure status before the infarction is related to survival. Hypertensive patients had almost three times the mortality of normotensive patients. Subjects who had hypertension after angina became clinically manifest had four times the mortality of those who were entirely normotensive.

REPORTS ON THERAPY

331 Comparative Hemodynamic Effects of Converting Enzyme Inhibitor and Sodium Nitroprusside in Severe Heart Failure

THOMAS R. VROBEL and JAY N. COHN

The acute hemodynamic response to the infusion of a nonspecific vasodilator, sodium nitroprusside, was similar to that of the converting enzyme inhibitor teprotide in nine patients with severe congestive heart failure. Both agents increased the cardiac index, reduced mean arterial pressure and pulmonary wedge pressure and produced no significant change in heart rate. The converting enzyme inhibitor, unlike nitroprusside, produced no significant change in arterial partial pressure of oxygen. This study shows that converting enzyme inhibitors produce an effect comparable with that of sodium nitroprusside but with less detrimental acute effect on pulmonary oxygen transport. Long-term oral therapy with converting enzyme inhibitors merits evaluation in patients with congestive heart failure.

337 Long-Term Therapy of Heart Failure With Prazosin: A Randomized Double Blind Trial

WILSON S. COLUCCI, JOSHUA WYNNE, B. LEONARD HOLMAN and EUGENE BRAUNWALD

Using a randomized, double blind protocol to evaluate the clinical effectiveness of 2 months of continuous prazosin therapy in 22 patients with severe congestive heart failure, these investigators found that the patients treated with prazosin, unlike the placebo-treated control patients, showed significant improvement in functional class, treadmill exercise duration, echocardiographic ejection fraction, stroke excursion, mean velocity of circumferential fiber shortening and ejection fraction measured with radionuclide ventriculography. Prazosin-treated patients had an increase in plasma renin activity and required an increase in diuretic dose. In patients with congestive heart failure prazosin appears to affect the sympathetic nervous system and the renin-angiotensin system, which influence the peripheral vascular bed directly and indirectly. After 2 months there was clinical evidence of attenuation of the initial response to prazosin, but the effect was only partial and did not preclude a sustained, clinically useful effect.

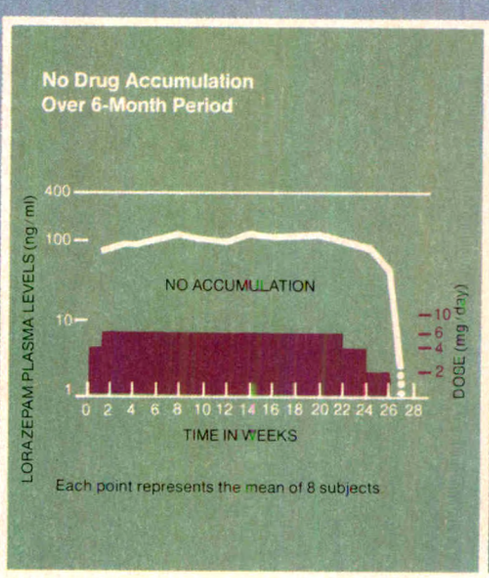
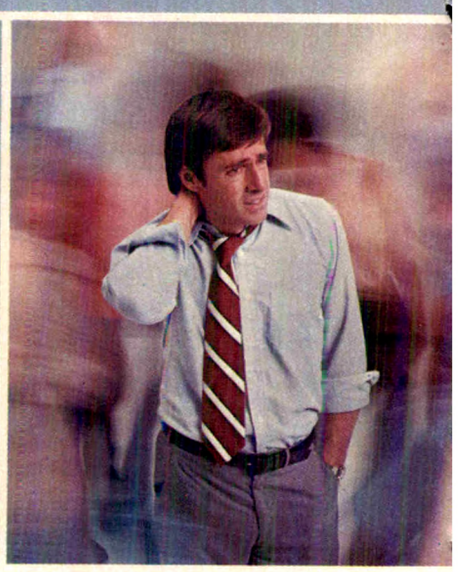
Cardiodyne

How do you choose a minor tranquilizer?





Wyeth Laboratories
Philadelphia, PA 19101

Pharmacokinetics

Ativan (lorazepam) is eliminated more rapidly than other benzodiazepines; generates no clinically active metabolites. The half-life of free lorazepam is about 12 hours; steady-state blood levels are attained in 2-3 days. (Comparable data for diazepam: 20-50 hours and at least 7-10 days.) Ativan shows no evidence of accumulation, even when given in high doses for as long as 6 months. (The pharmacokinetic profile of a drug can define such characteristics as absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Anxiety neuroses

In many nationwide studies involving thousands of patients with anxiety neuroses, Ativan (lorazepam) consistently provided significant relief of anxiety, tension, agitation and irritability as measured by standard Hamilton, Global (physician rated) and 35-Item (patient self-rated) scales.

Please visit us at Booth No. 810 at the ACC Scientific Session in Houston.

Copyright © 1979, Wyeth Laboratories Div. of AHPC, N.Y., N.Y. All rights reserved.

They're all about the same, aren't they? Until recently, that seemed to sum up the prevalent attitude about the benzodiazepines. After all, they all work similarly and all are effective anxiolytics. With seven of these compounds now available, however, differences have begun to emerge. Foremost among them: different metabolic pathways, which distinguish the relatively short-acting Ativan (lorazepam) from long-acting diazepam, clorazepate and chlordiazepoxide. At the same time, your choice can be made with confidence in the clinical record of Ativan, which confirms its value in anxiety neuroses and in significant anxiety associated with functional or organic disorders, as well as in older patients.

Consider the record of Ativan:

Anxiety in cardiovascular disorders

Ativan (lorazepam) has been specifically evaluated and found effective in seven common protocol, double-blind studies involving 423 patients (211 on Ativan) whose anxiety was related to organic and functional cardiovascular disorders. The cardiovascular component has not, of course, been shown to be significantly benefited by such therapy.

Anxiety in gastrointestinal disorders

So far, nine common protocol, double-blind studies of Ativan have focused on anxious patients with functional or organic gastrointestinal complaints (457 patients, 234 on Ativan). Ativan was clearly effective in reducing the anxiety of these patients. The gastrointestinal component has not, of course, been shown to be significantly benefited by such therapy.

Anxiety in the aging patient

Because its simple metabolism is not readily impaired with advancing age, and accumulation is not likely to present a problem, Ativan is a good choice for older patients. Those who have trouble swallowing solid medication appreciate the small Ativan tablet, which is tasteless and disintegrates within seconds in water or fruit juice.

Ativan® (lorazepam) for Anxiety

See important information on following page.

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability and insomnia associated with anxiety neuroses and transient situational disturbances; anxiety associated with depressive symptoms and as a treatment of symptoms of anxiety if such symptoms are a significant feature of functional or organic disorders, particularly gastrointestinal or cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatric patients requires caution and frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring of vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for (lorazepam) Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

NITROSTAT®
(nitroglycerin tablets, USP)

INDICATIONS
Nitrostat is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally, particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

0.15 mg (1/400 grain): N 0071-0568-24 [06]—Ctn. of 10 bottles of 100 tablets; N 0071-0568-13—Convenience Package.

0.3 mg (1/200 grain): N 0071-0569-24 [06]—Ctn. of 10 bottles of 100 tablets; N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain): N 0071-0570-24 [06]—Ctn. of 10 bottles of 100 tablets; N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain): N 0071-0571-24 [06]—Ctn. of 10 bottles of 100 tablets; N 0071-0571-13—Convenience Package. **YF**

PD-JA-2810-1-P (7-79)

At the critical times of an angina attack...

NITROSTAT®

(nitroglycerin tablets, USP)

4x25s

- ☐ allows your patient to store one bottle of Nitrostat 25s for immediate use at four different locations
- ☐ is more stable than conventional nitroglycerin tablets
- ☐ has an average assay better than 100% of label claim for at least 60 months after manufacture*
- ☐ is useful as sole therapy; is useful as concomitant therapy with long-acting nitrates and/or propranolol hydrochloride

*Five-year expiration date when stored at recommended conditions in an unopened bottle.
Data on file, Parke-Davis.

CONTENTS

345 Early Repair of Ventricular Septal Rupture After Infarction

ALVARO MONTOYA, LOUIS McKEEVER, PATRICK SCANLON, HENRY J. SULLIVAN, ROLF M. GUNNAR and ROQUE PIFARRÉ

In this series of 27 consecutive patients, aged 40 to 78 years with ventricular rupture during acute myocardial infarction, the time from myocardial infarction to rupture was less than 24 hours in 9 patients, 24 to 48 hours in 6 patients, 2 to 7 days in 11 patients and 14 days in 1 patient. Myocardial infarction was posteroinferior in 16 patients and anterior in 11. In this group early operation in ventricular septal rupture had a relatively low mortality; invasive study and surgery were delayed at the expense of unacceptable and unpredictable mortality; and ventricular septal rupture occurred in eight patients with single vessel disease. All seven patients who were not operated on died. Patients with anterior infarction had a better prognosis than those with inferior infarction; 73 percent of the former survived the operation, compared with only 33 percent of the latter. When technically possible, aortocoronary bypass to all significantly obstructed vessels should be performed.

COOPERATIVE STUDIES

349 Clinical Assessment of External Pressure Circulatory Assistance in Acute Myocardial Infarction: Report of a Cooperative Clinical Trial

EZRA A. AMSTERDAM, JOHN BANAS, J. MICHAEL CRILEY, HENRY S. LOEB, HILTRUD MUELLER, JAMES T. WILLERSON and DEAN T. MASON

Application of external pressure circulatory assistance during the first 24 hours after the onset of symptoms of myocardial infarction was associated with a significant reduction in hospital mortality and morbidity in 142 patients with mild left ventricular failure as compared with findings in a matched control group of 116 patients studied in 26 hospitals. The clinical benefits of external pressure circulatory assistance were closely related to the duration of this therapy (4 or more hours) administered in the 24 hours after the clinical onset of acute myocardial infarction. Complications were limited to discomfort of the legs, which occasionally may preclude this therapy, but there was no evidence of local trauma. Further assessment of the effects of the treatment on myocardial ischemia and infarct size is warranted.

REVIEWS

357 Fungal Infections of the Heart: Analysis of 51 Autopsy Cases

THOMAS J. WALSH, GROVER M. HUTCHINS, BERNADINE H. BULKLEY and GEOFFREY MENDELSOHN

Cardiac fungal infections at autopsy were found in 51 patients at the Johns Hopkins Hospital between the years 1954–1977. In only one case was this condition diagnosed during life. The infecting organisms included Candida (34), Aspergillus (13), Cryptococcus (3) and combined Candida and Aspergillus (1). Predisposing conditions were abdominal surgery (20), thoracic surgery (7) and treatment with corticosteroids and antineoplastic or antibiotic drugs (43), alone or in combination. Therapeutic results of cardiac fungal infection remain dismal. Early diagnosis is difficult but crucial to successful treatment. Synergism between amphotericin B and 5-fluorocytosine makes this combination worthwhile to use in patients with serious candidal infections.

HISTORICAL MILESTONES

367 John Hunter, Angina Pectoris and Medical Education

PAUL KLIGFIELD

This Milestone credits Edward Jenner, best known as the discoverer of vaccination, as the originator of the coronary arterial theory of angina pectoris. In 1785 Jenner described coronary artery disease as the cause of angina pectoris but refrained from publishing this observation out of deference to John Hunter, his former teacher who suffered from effort-related and anxiety-induced angina. Jenner feared "it would deprive him (Hunter) of the hopes of a recovery." When John Hunter died, after an emotional conflict partly arising from academic teaching problems, his "coronary arteries of the heart were considerably ossified." The complaints of the 18th century pupils that partially precipitated this conflict serve as a reminder of the necessary supervision and attention required by students, even today.

DIAGNOSTIC SHELF

370 Two Dimensional Echocardiographic Visualization of Ventricular Septal Rupture After Acute Anterior Myocardial Infarction

JEAN C. FARCOT, LOUIS BOISANTE, MICHEL RIGAUD, JEAN BARDET and JEAN P. BOURDARIAS

This paper reports that two dimensional echocardiographic findings in three consecutive cases of ventricular septal defect after acute myocardial infarction permitted the defect to be localized and its size estimated. The

Burdick introduces the 38-second electrocardiogram.

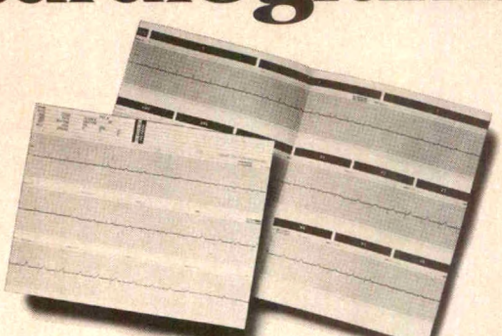
In fact, only 37.4 seconds to record the complete 12-lead electrocardiogram. It's the new EK-8, Burdick's first fully automatic single-channel electrocardiograph.

Combined with its new and unique mounting system, the EK-8 assures higher ECG productivity, substantial savings of time for operator and staff, and important savings on ECG paper.

Each lead is recorded in proper sequence—with lead lengths and lead switching on every lead automatically controlled. With proper technic there is no stopping to move the chest lead, fewer overruns, less waste, more ECG's per roll. That means additional savings.

Important savings of technician and staff time are possible with the EK-8's unique mounting system. Leads are automatically identified, and the complete 12-lead tracing is ready for mounting on Burdick self-adhesive card or folder formats, ready for filing. In the folder-mode, with longer leads for additional data, the complete ECG is recorded in 47.1 seconds. Manual override provides full choice of lead lengths if desired.

The new, faster Burdick EK-8. Because time is your valuable asset for better patient service. For more information, or a demonstration, call us toll-free at 800-356-0701. In Wisconsin call 608-868-7631. Or write **The Burdick Corporation, Milton, Wisconsin 53563.**



Burdick card and folder-format mounts—fast, efficient way to mount and file ECGs.

BURDICK

A concern for cardiac care.

Announcing the formation of

Berlex Laboratories Inc.

a new pharmaceutical company that will offer the best of two worlds

Dear Doctor:

You are familiar with the product that appears on the opposite page, but you are not familiar with the company name that now appears on that product, Berlex Laboratories Inc.

Berlex Laboratories Inc. is the new American subsidiary of Schering AG, Berlin, West Germany, one of the world's most respected research-oriented pharmaceutical manufacturers, with a history of innovation and excellence dating back to 1851. Schering AG is not connected with Schering-Plough Corporation, Kenilworth, New Jersey.

Berlex Laboratories was formed through the acquisition of certain products and manufacturing and research facilities of Cooper Laboratories, Inc. The more familiar preparations in the specialties of cardiology, internal medicine, allergy and general medicine include:

Aminodur® Dura-Tabs® (aminophylline)
Deconamine® (chlorpheniramine maleate/d-pseudoephedrine hydrochloride)
Elixophyllin® (theophylline)
Elixicon® Suspension (theophylline)
Kay Ciel® (potassium chloride)
Pyocidin-Otic® (polymyxin-hydrocortisone)
Quinaglute® Dura-Tabs® (quinidine gluconate)
Sus-Phrine® (epinephrine)
Therapav® (papaverine hydrochloride)

In the future, Berlex Laboratories plans to augment these well-established products with others not currently available in the United States but which have gained high acceptance by physicians around the world. Berlex Laboratories' parent company manufactures and distributes over 100 ethical products through 120 plants and subsidiaries in 140 countries.

Although you are unfamiliar with our name now, you will soon know us as physicians in other countries know and respect our parent company.

Berlex Laboratories looks forward to serving you with products developed by our worldwide research resources. Products to meet the challenges of tomorrow will come from commitment to research today. Berlex Laboratories Inc. is making that commitment now to meet the challenges of tomorrow.

BERLEX Laboratories Inc.

When the compromised arrhythmic patient needs round-the-clock, year-after-year protection

Quinaglute® 324 mg DURA-TABS®
(quinidine gluconate)®

CONTRAINDICATIONS:
Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.
Partial A-V or complete heart block, or intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening.
Renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defects, ventricular premature beats, ventricular tachycardia or flutter while on the drug.
Marked cardiac enlargement, particularly with congestive failure, poor renal function, and especially renal tubular acidosis.
Idiosyncrasy or hypersensitivity to quinidine.
WARNINGS:
In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate.
PRECAUTIONS:
The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy.
Quinidine in large doses may reduce the contractile force of the heart, therefore, extreme caution should be exercised in using the drug in patients with severe heart disease, hypotension or digitalis intoxication. The potential disadvantages and benefits must be weighed.
It should be administered cautiously, if at all, to senile patients.
Hospitalization for close clinical observation, electrocardiographic monitoring, and possibly plasma quinidine levels is indicated when large doses are used or with patients who present an increased risk.
ADVERSE REACTIONS:
Symptoms of cinchonism, ringing in ears, headache, nausea, disturbed vision may appear in sensitive patients after a single dose of the drug.
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism, hypotension.
Gastrointestinal: Nausea, vomiting, abdominal pain, diarrhea.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision fields, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Cutaneous flushing with intense pruritus.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest.
See package insert for full information.

septal rupture was subsequently confirmed at operation in two patients and on postmortem examination in the third patient. Postoperative echocardiographic studies afforded demonstration of the patch closing the defect. Negative contrast echoventriculography identified a left to right shunt at the ventricular level. These cases demonstrate the value of this simple noninvasive method for diagnosing promptly septal perforation and permitting surgical repair before severe deterioration of the patient's condition.

378 **Early Diastolic Sound of Constrictive Pericarditis**

W. JAY NICHOLSON, B. WOODFIN COBBS, Jr., ROBERT H. FRANCH and I. SYLVIA CRAWLEY

An early diastolic sound or "pericardial knock" occurring 0.09 to 0.16 second after the second heart sound is present in 30 to 70 percent of cases of constrictive pericarditis. In these two patients with calcific constrictive pericarditis such an absent or faint early diastolic sound became prominent both with squatting, which increases peripheral resistance and venous return, and with phenylephrine infusion or injection of contrast medium; it was obliterated by nitroglycerin. Maneuvers that elicited the early diastolic sound were constantly accompanied by a deepening of the diastolic dip, but the amount of change often seemed modest in proportion to the intensification of sound, suggesting that its production is a threshold event.

CASE REPORTS

383 **Mitral Valve Prolapse: Jet Stream Causing Mural Endocarditis**

MORRIS RINGER, DENNIS J. FEEN and MARK S. DRAPKIN

This interesting case illustrates how endocarditis may be the initial presentation of mitral valve prolapse and may end fatally as it did in this 53 year old man. At autopsy the only endocarditic lesion was on the left atrial mural endocardium, against which the regurgitant jet stream was directed as a result of spontaneous rupture of the anterior mitral valve chordae tendineae. This lesion became infected with streptococcus mutans consequent to transient bacteremia, probably from a dental source. Subsequent septic cerebral embolization caused death.

386 **Clotted Hemopericardium With the Hemodynamic Characteristics of Constrictive Pericarditis**

WILLIAM C. LITTLE, R. KIRBY PRIMM, ROBERT B. KARP and WILLIAM P. HOOD, Jr.

This case illustrates that clotted hemopericardium need not produce the classic hemodynamic and clinical features of cardiac tamponade but may mimic constrictive pericarditis. Four weeks after three vessel coronary arterial bypass surgery this 65 year old man had a syncopal episode. Cardiac catheterization demonstrated the typical hemodynamic findings of constrictive pericarditis which completely resolved after 500 ml of clotted blood was removed and the pericardium was left in place. When clotted hemopericardium is a possibility, the lack of marked pulsus paradoxus and the presentation of a right atrial *Y* descent may not rule out hemopericardium as a cause of hemodynamic impairment.

Introducing the Datascope Hospital System.

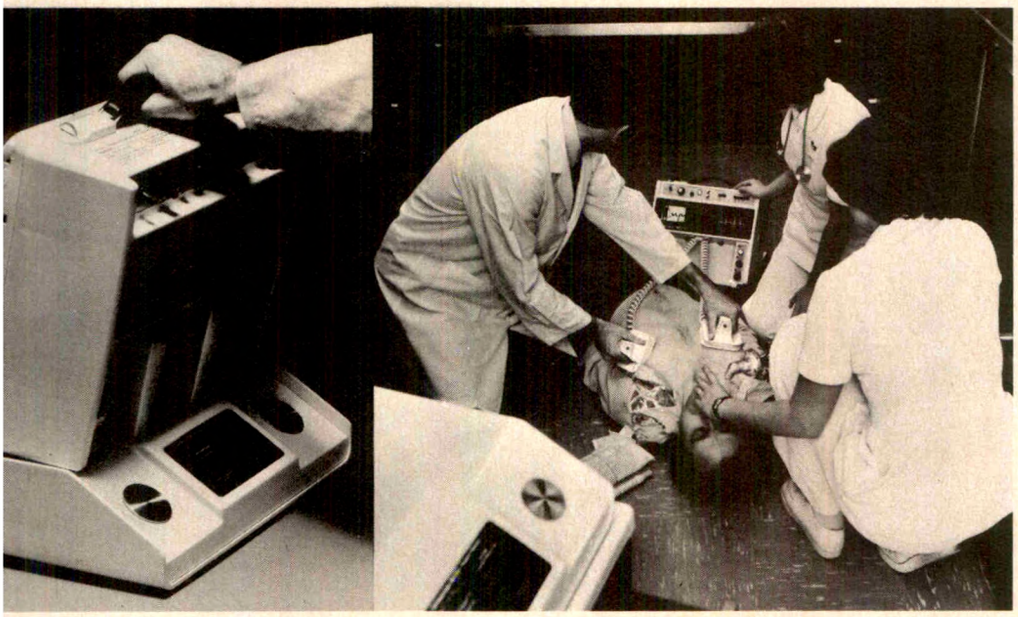
The most advanced defibrillator system ever put on a crash cart. Or ever taken off one.

Defibrillators for the spital have always been a npromise.

Those designed for a crash t are difficult to use away from crash cart because they're so ıvy and unwieldy.

And the portables, while ering more portability, don't ve the capability of their ıvier counterparts.

You've had to choose ween performance and porta-ity. Until now, you couldn't ve both.



We're pleased to offer you first defibrillator system ıt doesn't force you to com-ɔmise: the Datascope Hospital stem.

The Datascope Hospital stem is the M/D3 defibrillator/ ɔnitor/recorder and the support ɔdule in which it nests.

Since you may need a ibrillator on a cart, or a rtable to reach and transport a ient, we designed the M/D3 like other defibrillators.

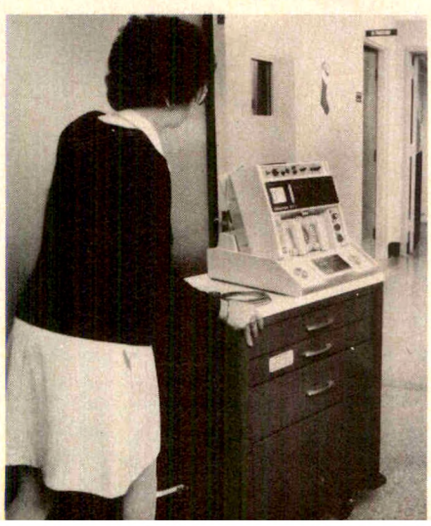
The Datascope Hospital stem separates in a manner that ıkes sense. The defibrillator, ɔnitor and recorder all remain act as a compact unit. So you vays have everything you need with you where you need it, when you need it. The support module separates and remains on the crash cart, leaving unnecessary weight behind.

On or off a crash cart, it has features found in no other system.

The scope on the Hospital System is 5″ in diameter. The same size as scopes on defibrillators weighing 35 to 40 pounds.

The monitor offers 2 large digital displays. One for heart rate and one for delivered energy. (To our mind, lights are simply not an adequate indication of such critical parameters.)

The support module for the Datascope Hospital System has a built-in delivered energy tester. Here again, instead of a light that merely indicates, there's a meter that accurately measures the delivered energy throughout the entire range of the defibrillator.



There's a document switch on the defibrillator paddles to trigger the strip chart recorder. And the paddles rapidly disconnect for easy changes or replacement.

Perhaps the most important innovation of all, ours is the first defibrillator system to end the fear of battery failure.

The M/D3 incorporates three totally independent power systems: complete ac line operation, nickel-cadmium batteries that recharge in less than five hours, and the world first Lithium Emergency Power Pack. This revolutionary power pack remains fully-charged in the unit for up to 5 years. In the event that all other power sources fail, you merely activate the Emergency Pack to instantly power the monitor and defibrillator.

For all of its features, the M/D3 weighs less than 28 pounds and is extremely easy to operate.

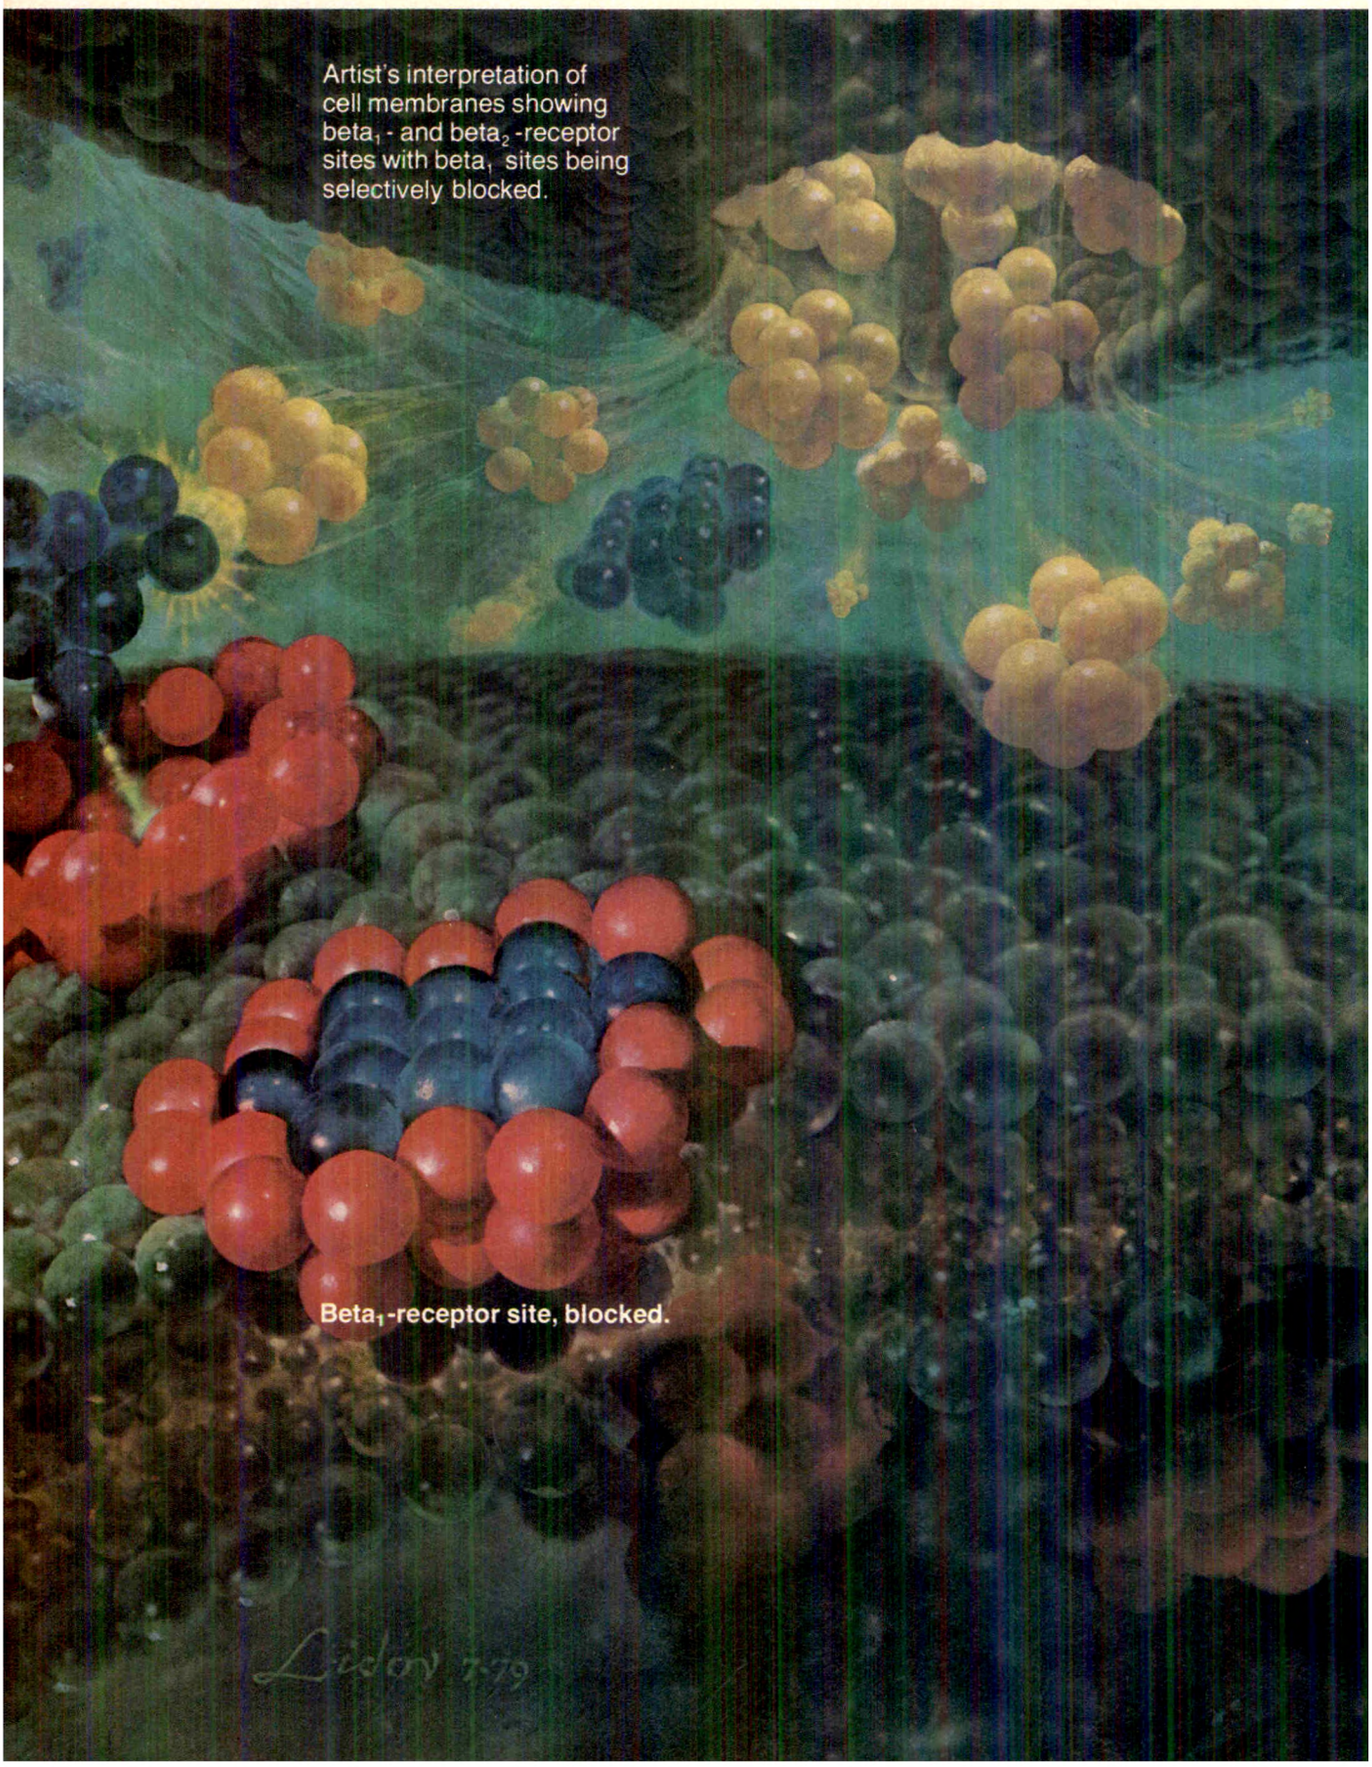
We urge you to see a demonstration of the new Datascope Hospital System. There has never been any defibrillator in a hospital like it. On or off a crash cart.

To arrange for a demonstration call us at 201-265-8800. Datascope Corp., Box 5-AA, Paramus, NJ 07652. In Europe: Datascope B.V., Post Box 26, 3870 CA, Hoevelaken, Holland.

The Datascope M/D3 Hospital System

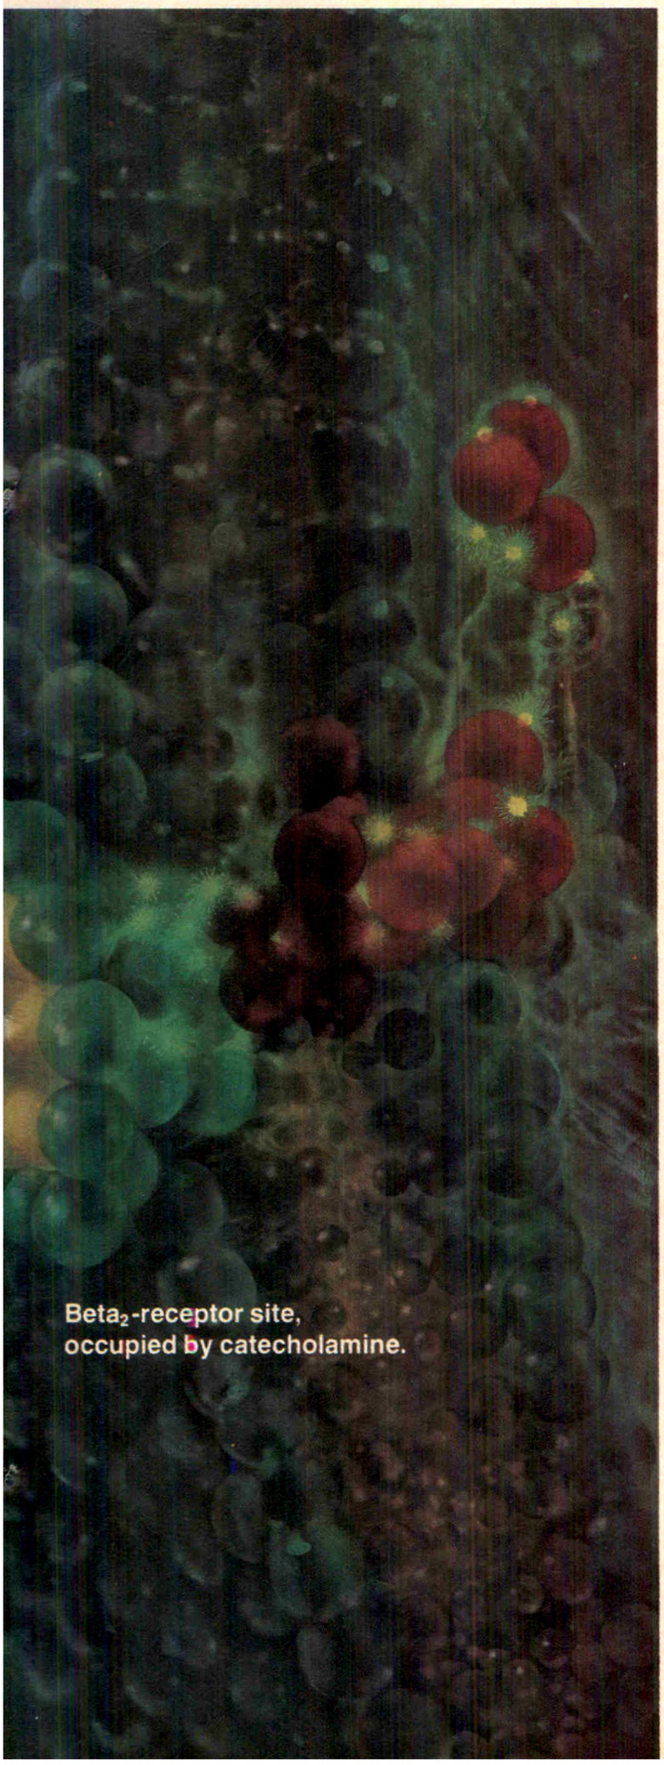
See us at Booth Nos. 433, 435 & 437 at the ACC, March 10–13 in Houston.

the preferential effect



Lopressor®
metoprolol tartrate

works where it should—not where it shouldn't in hypertension



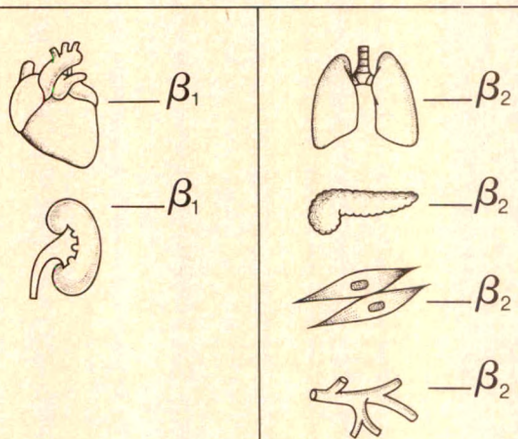
Beta$_2$-receptor site, occupied by catecholamine.

The beta blocker with a significant preference for beta$_1$ receptors in the heart*

Lopressor represents a major step forward in more specific beta blockade.

Unlike the nonselective beta blocker, propranolol, which indiscriminately blocks both beta$_1$ and beta$_2$ adrenoreceptors, Lopressor is relatively selective, that is, it exerts a preferential effect on beta$_1$ receptors in the heart—those involved in lowering blood pressure. Lopressor, at usual therapeutic doses, has a much lower affinity for beta$_2$ receptors.

Beta$_1$-and beta$_2$-receptor sites



Works where it should... not where it shouldn't.

*Hansson L, Werkö L: Beta-adrenergic blockade in hypertension. Am Heart J 93(3):394-402 (Mar.) 1977.

Please see next page for brief prescribing information.

Geigy

Lopressor®
metoprolol tartrate

works where it should... not where it shouldn't

Very well tolerated

- unlike traditional sympathetic inhibitors, there is usually no sedation, sexual dysfunction or postural hypotension with Lopressor
- most side effects mild and transient

The most frequently reported adverse reactions (which occurred in approximately ten out of 100 patients) are tiredness and dizziness. Depression and diarrhea have occurred in about five out of 100. Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure.

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System. Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Printed in U.S.A. 667292 (8/79) C79-22

WHEN YOU SUSPECT OR DETEC VENOUS THROMBOSIS...

Thromboembolism: a high risk among patients with one or more of these factors...

Advanced age
Fractures of lower limb
Hip surgery
Pelvic or abdominal surgery with extensive dissection
Previous venous thromboembolism
Congestive cardiac failure
Cancer surgery
Obesity
Varicose vein surgery

Incidence of venous thrombosis or abnormal scans as shown by ^{125}I-fibrinogen screening in selected high-risk medical-surgical patients

Category	Incidence
Elective surgery	
Major abdominal thoracic/gynecologic	11-65%[1,2]
Retropubic prostatectomy	28-50%[1,2]
Transurethral prostatectomy	4%[1,2]
Emergency surgery	
Hip fracture	48-74%[1,2]
Childbirth	3%[1,2]
Medical	
Myocardial infarction	23-38%[1,2]
Stroke	60%[1]

ORAL ANTICOAGULATION:
Often indicated to lower the risk of thromboembolic complications.

References: 1. Hirsh J, Gallus AS: ^{125}I-labeled fibrinogen scanning. *For selected patients who have had a large infarct, a history of previous infarction or angina, severe hypotension or shock, chronic atrial fibrillation, congestive heart failure, past history of venous thrombosis or embolism or complications requiring a prolonged period in bed.

Endo Laboratories DUPONT

COUMADIN is an Endo registered U.S. trademark.

The oral anticoagulant of choice:

Tablets
COUMADIN®
crystalline warfarin sodium

singled out by more than 20 years of experience

Effective prophylaxis and treatment of venous thrombosis
Effective prophylaxis and treatment of pulmonary embolism
Effective treatment of atrial fibrillation with embolization
Effective adjunctive treatment of coronary occlusion

Initiation of therapy

Induction – 40 to 60 mg for average adult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Alternatively, the large priming dose may be decreased for all patients to minimize the possibility of excessive increases in prothrombin time. Induction may be initiated with 10 to 15 mg daily and thereafter (usually 2 or 3 days) adjusted according to prothrombin time response.

- dosage must be individualized according to patient's prothrombin time
- frequent laboratory monitoring is recommended
- determine prothrombin time daily until results fall within the therapeutic range – 1.5 to 2.5 times normal
- afterwards, prothrombin time must be determined periodically to monitor the patient's course

Maintenance of anticoagulation

- 2-10 mg, for most patients (scored tablets allow flexibility and accurate titration)
- dose and interval should be adjusted according to the individual patient's prothrombin time response

Duration of anticoagulation

- should be individualized for each patient
- in general, should be continued until danger of thrombosis and embolism has passed

Recommendations of prominent clinicians on duration of therapy

in myocardial infarction[3,4*]	1-3 years* (reevaluate at least every 6 months)
in pulmonary embolism[4,5]	6 weeks-6 months
in deep vein thrombosis[4,5]	6 weeks-6 months

Before prescribing, please see full product information on next page.

COUMADIN® Tablets
for long- and short-term oral anticoagulation...
crystalline warfarin sodium, U.S.P.*

DESCRIPTION COUMADIN (crystalline warfarin sodium), a prothrombinopenic anticoagulant, is chemically crystalline sodium warfarin isopropanol clathrate. The crystallization of warfarin sodium virtually eliminates trace impurities present in amorphous warfarin sodium, thus achieving a crystalline product of the highest purity. Warfarin* is the coined generic name for 3-(α-Acetonylbenzyl)-4-hydroxycoumarin. On a dose-for-dose basis, COUMADIN (crystalline warfarin sodium) is therapeutically equivalent to amorphous warfarin sodium.

ACTIONS COUMADIN and other coumarin anticoagulants act by depressing synthesis in the liver of several factors which are known to be active in the coagulation mechanisms in a variety of diseases characterized by thromboembolic phenomena. The resultant **in vivo** effect is a sequential depression of Factors VII, IX, X and II. The degree of depression is dependent upon the dosage administered. Anticoagulants have no direct effect on an established thrombus, nor do they reverse ischemic tissue damage. However, once a thrombosis has occurred, anticoagulant treatment aims to prevent further extension of the formed clot and prevents secondary thromboembolic complications which may result in serious and possible fatal sequelae.

After oral administration, absorption is essentially complete, and maximal plasma concentrations are reached in 1 to 9 hours. Approximately 97% is bound to albumin within the plasma. COUMADIN usually induces hypoprothrombinemia in 36 to 72 hours, and its duration of action may persist for 4 to 5 days, thus producing a smooth, long lasting response curve. Little is known of the metabolic pathways involved in the biotransformation of oral anticoagulants in man. However, their metabolites appear to be eliminated principally in the urine.

INDICATIONS Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: COUMADIN is indicated for the prophylaxis and treatment of venous thrombosis and its extension, the treatment of atrial fibrillation with embolization, the prophylaxis and treatment of pulmonary embolism, and as an adjunct in the treatment of coronary occlusion.

"Possibly" effective: as an adjunct in the treatment of transient cerebral ischemic attacks.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATIONS Anticoagulation is contraindicated in any localized or general physical condition or personal circumstance in which the hazard of hemorrhage might be greater than its potential clinical benefits, such as:

Pregnancy—COUMADIN is contraindicated in pregnancy because the drug passes through the placental barrier and may cause fatal hemorrhage to the fetus in utero. Furthermore, there have been reports of birth malformations in children born to mothers who have been treated with warfarin during pregnancy. Women of childbearing potential who are candidates for anticoagulant therapy should be carefully evaluated and the indications critically reviewed with the patient. If the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the possibility of termination of the pregnancy should be discussed in light of those risks.

Hemorrhagic tendencies or blood dyscrasias. Recent or contemplated surgery of: (1)central nervous system; (2)eye; (3)traumatic surgery resulting in large open surfaces. **Bleeding tendencies associated with active ulceration or overt bleeding of:** (1)gastrointestinal, genitourinary or respiratory tracts, (2)cerebrovascular hemorrhage, (3)aneurysms—cerebral, dissecting aorta, (4)pericarditis and pericardial effusions, (5)subacute bacterial endocarditis. **Threatened abortion,** eclampsia and preeclampsia. **Inadequate laboratory facilities** or unsupervised senility, alcoholism, psychosis, or lack of patient cooperation. **Spinal puncture** and other diagnostic or therapeutic procedures with potential for uncontrollable bleeding. **Miscellaneous:** major regional, lumbar block anesthesia and malignant hypertension.

WARNINGS Warfarin sodium is a potent drug with a half-life of 2½ days; therefore its effects may become more pronounced as daily maintenance doses overlap. It cannot be emphasized too strongly that treatment of each patient is a highly individualized matter. Dosage should be controlled by periodic determinations of prothrombin time or other suitable coagulation tests. Determinations of whole blood clotting and bleeding times are not effective measures for control of therapy. Heparin prolongs the one-stage prothrombin time. Therefore, to obtain a valid prothrombin time when heparin and COUMADIN are given together, a period of at least 5 hours should elapse after the last intravenous dose and 24 hours after the last subcutaneous dose of heparin, before blood is drawn.

Caution should be observed when warfarin sodium is administered in any situation or physical condition where added risk of hemorrhage is present.

Administration of anticoagulants in the following conditions will be based upon clinical judgment in which the risks of anticoagulant therapy are weighed against the risk of thrombosis or embolization in untreated cases. The following may be associated with these increased risks:

Lactation—coumarins may pass into the milk of mothers and cause a prothrombinopenic state in the nursing infant. **Severe to moderate hepatic or renal insufficiency. Infectious diseases or disturbances of intestinal flora**—sprue, antibiotic therapy. **Trauma** which may result in internal bleeding. **Surgery or trauma** resulting in large exposed raw surfaces. **Indwelling catheters. Severe to moderate hypertension. Miscellaneous:** polycythemia vera, vasculitis, severe diabetes, severe allergic and anaphylactic disorders.

Patients with congestive heart failure may become more sensitive to COUMADIN, thereby requiring more frequent laboratory monitoring, and reduced doses of COUMADIN.

Concurrent use of anticoagulants with streptokinase or urokinase is not recommended and may be hazardous. (Please note recommendations accompanying these preparations.)

Abrupt cessation of anticoagulant therapy is not generally recommended; taper dose gradually over three to four weeks.

PRECAUTIONS Periodic determination of prothrombin time or other suitable coagulation test is essential.

Numerous factors, alone or in combination, including travel, changes in diet, environment, physical state and medication may influence response of the patient to anticoagulants. It is generally good practice to monitor the patient's response with additional prothrombin time determinations in the period immediately after discharge from the hospital, and whenever other medications are initiated, discontinued or taken haphazardly. The following factors are listed for your reference; however, other factors may also affect the prothrombin response.

The following factors, alone or in combination, may be responsible for increased prothrombin time response:

ENDOGENOUS FACTORS: Carcinoma, collagen disease; congestive heart failure; diarrhea; elevated temperature; hepatic disorders—infectious hepatitis, jaundice; poor nutritional state; vitamin K deficiency—steatorrhea.

EXOGENOUS FACTORS: Alcohol†; allopurinol; aminosalicylic acid; anabolic steroids; antibiotics; bromelains; chloral hydrate†; chlorpropamide; chymotrypsin; cimetidine; cinchophen; clofibrate; COUMADIN (crystalline warfarin sodium) overdosage; dextran; dextrothyroxine; diazoxide; dietary deficiencies; diuretics†; disulfiram; drugs affecting blood elements; ethacrynic acid; glucagon; hepatotoxic drugs; indomethacin; inhalation anesthetics; mefenamic acid; methyldopa; methylphenidate; metronidazole; monoamine oxidase inhibitors; nalidixic acid; oxolinic acid; oxyphenbutazone; phenylbutazone; phenyramidol; prolonged hot weather; prolonged narcotics; quinidine; quinine; salicylates; sulfinpyrazone; sulfonamides, long acting; thyroid drugs; tolbutamide; triclofos sodium; trimethoprim/sulfamethoxazole; unreliable prothrombin time determinations.

The following factors, alone or in combination, may be responsible for decreased prothrombin time response:

ENDOGENOUS FACTORS: Diabetes mellitus; edema; hereditary resistance to coumarin therapy; hyperlipemia; hypothyroidism.

EXOGENOUS FACTORS: Adrenocortical steroids; alcohol†; antacids; antihistamines; barbiturates; chloral hydrate†; chlordiazepoxide; cholestyramine; COUMADIN underdosage; diet high in vitamin K (vegetables, fish, fish oil, onions); diuretics†; ethchlorvynol; glutethimide; griseofulvin; haloperidol; meprobamate; oral contraceptives; paraldehyde; primidone; rifampin; unreliable prothrombin time determinations; vitamin C.

†Increased and decreased prothrombin time responses have been reported.

*Present as crystalline sodium warfarin isopropanol clathrate.

A patient may be exposed to a combination of the above factors, some of which may increase and some decrease his sensitivity to COUMADIN. Because the net effect on his prothrombin time response may be unpredictable under these circumstances, more frequent laboratory monitoring is advisable.

Drugs not yet shown to interact or not to interact with coumarins are best regarded with suspicion, and when their administration is started or stopped, the prothrombin time should be determined more often than usual.

Coumarins also affect the action of other drugs. Hypoglycemic agents (chlorpropamide and tolbutamide) and anticonvulsants (diphenylhydantoin and phenobarbital) may accumulate in the body as a result of interference with either their metabolism or excretion.

ADVERSE REACTIONS Potential side effects of COUMADIN (crystalline warfarin sodium) include:

1. Minor or major hemorrhage from any tissue or organ—which is an extension of the physiologic activity of prothrombinopenia. The signs and symptoms will vary according to the location and degree or extent of the bleeding. Therefore the possibility of hemorrhage should be considered in evaluating the condition of any anticoagulated patient with complaints which do not indicate an obvious diagnosis. Bleeding during anticoagulant therapy does not always correlate with prothrombin activity. (See TREATMENT FOR OVERDOSAGE.)

Bleeding which occurs when the prothrombin time is within the therapeutic range warrants diagnostic investigation since it may unmask a previously unsuspected lesion, e.g. tumor, ulcer, etc.

2. Side effects other than hemorrhage are infrequent and consist of alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramping, a syndrome called "purple toes," hypersensitivity reactions and a reaction consisting of hemorrhagic infarction and necrosis of the skin.

3. Priapism has been associated with anticoagulant administration, however, a causal relationship has not been established.

DOSAGE AND LABORATORY CONTROL The aim of anticoagulant therapy is to impede the coagulation or clotting mechanism to such an extent that thrombosis will not occur, but at the same time avoiding such extensive impairment as might produce spontaneous bleeding. Effective therapeutic levels with minimal complications can best be achieved in cooperative and well-instructed patients, who keep the doctor informed of their status between visits. COUMADIN patient aids are available to physicians on request.

The administration and dosage of COUMADIN must be individualized for each patient according to the particular patient's sensitivity to the drug as indicated by the prothrombin time. The prothrombin time reflects the depression of vitamin K dependent Factors VII, X and II. These factors, in addition to Factor IX, are affected by coumarin anticoagulants. There are several modifications of the Quick one-stage prothrombin time and the physician should become familiar with the specific method used in his laboratory.

Administration of COUMADIN should be gauged according to prothrombin time determinations by a suitable method. The blood prothrombin time should usually be determined daily after the administration of the initial dose until prothrombin time results stabilize in the therapeutic range. Intervals between subsequent prothrombin time determinations should be based upon the physician's judgment of the patient's reliability and response to warfarin in order to maintain the individual within the therapeutic range. Acceptable intervals for prothrombin time determinations have usually fallen within the range of one to four weeks. Satisfactory levels for maintenance of therapeutic anticoagulation are 1½ to 2½ times the normal prothrombin time (e.g. 18 to 30 seconds, with a control of 12 seconds).

Induction—40 to 60 mg for average adult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Alternatively, the large priming dose may be decreased for all patients to minimize the possibility of excessive increases in prothrombin time. Induction may be initiated with 10 to 15 mg daily and thereafter (usually 2 or 3 days) adjusted according to prothrombin time response. The basis for the no-loading dose regimen is that the depression of Factors II, IX, and X are not accelerated by the administration of a loading dose.

Maintenance—Most patients are satisfactorily maintained at a dose of 2 to 10 mg daily. Flexibility of dosage is provided by breaking scored tablets in half. The individual dose and interval should be gauged by the patient's prothrombin response.

Duration of therapy—The duration of therapy in each patient should be individualized. In general, anticoagulant therapy should be continued until the danger of thrombosis and embolism has passed.

Treatment during dentistry and surgery—The management of patients who undergo dental and surgical procedures requires close liaison between attending physicians, surgeons and dentists. Interruption of anticoagulant therapy may precipitate thromboembolism, and conversely, if anticoagulants are maintained at full doses, some patients may hemorrhage excessively. If it is elected to administer anticoagulants prior to, during, or immediately following dental or surgical procedures, it is recommended that the dosage of COUMADIN (crystalline warfarin sodium) be adjusted to maintain the prothrombin time at approximately 1½ to 2½ times the control level. The operative site should be sufficiently limited to permit the effective use of local procedures for hemostasis including absorbable hemostatic agents, sutures, and pressure dressings if necessary. Under these conditions dental and surgical procedures may be performed without undue risk of hemorrhage.

COUMADIN with Heparin—Since a delay intervenes between the administration of the initial dose and the therapeutic prolongation of prothrombin time, it may be advisable in emergency situations to administer sodium heparin initially along with COUMADIN. The initial dose of heparin and injectable COUMADIN may be administered together in the same syringe. It should be noted that heparin may affect the prothrombin time, and therefore, when patients are receiving both heparin and COUMADIN, the blood sample for prothrombin time determination should be drawn just prior to the next heparin dosage, at least 5 hours after the last intravenous injection or 24 hours after the last subcutaneous injection.

TREATMENT FOR OVERDOSAGE Excessive prothrombinopenia, with or without bleeding, is readily controlled by discontinuing COUMADIN (crystalline warfarin sodium), and if necessary, the oral or parenteral administration of vitamin K_1. The appearance of microscopic hematuria, excessive menstrual bleeding, melena, petechiae or oozing from nicks made while shaving are early manifestations of hypoprothrombinemia beyond a safe and satisfactory level.

In excessive prothrombinopenia with mild or no bleeding, omission of one or more doses of COUMADIN may suffice; and if necessary, small doses of vitamin K_1 orally, 2.5 to 10 mg, will usually correct the problem.

If minor bleeding persists, or progresses to frank bleeding, vitamin K_1 in doses of 5 to 25 mg may be given parenterally. (Please note recommendations accompanying vitamin K preparations prior to use.)

Fresh whole blood transfusions should be considered in cases of severe bleeding or prothrombinopenic states unresponsive to vitamin K_1.

Resumption of COUMADIN administration reverses the effect of vitamin K_1, and a therapeutic hypoprothrombinemia level can again be obtained.

SUPPLIED Tablets: COUMADIN (crystalline warfarin sodium). For oral use; single scored, imprinted numerically with potency as follows: 2 mg lavender, 2½ mg orange, 5 mg peach, 7½ mg yellow, 10 mg white. In bottles of 100 and 1000. Also available in Hospital Unit-Dose blister package of 100.

Injection: Available as single injection units of amorphous warfarin sodium lyophilized for intravenous or intramuscular use in a box of 6 units for use immediately after reconstitution.

50 mg: Unit consists of 1 vial, 50 mg; sodium chloride, 10 mg; thimerosal, 0.2 mg; pH is adjusted with sodium hydroxide; accompanied by a 2 ml ampul Sterile Water for Injection.

Sterile Water for Injection contains no antimicrobial or other substance, and it is not suitable for intravascular injection without first having been made approximately isotonic by the addition of a suitable solute. Use only for reconstitution of the lyophilized product.

LANOXIN®
(DIGOXIN)
TABLETS
0.125 mg Scored (yellow), I.D. Imprint Y3B
0.25 mg Scored (white), I.D. Imprint X3A
0.5 mg Scored (green), I.D. Imprint T9A

LANOXIN®
(DIGOXIN)
ELIXIR PEDIATRIC
50 mcg (0.05 mg) per cc

INDICATIONS:

1. Congestive heart failure: Congestive heart failure, all degrees, is the primary indication. The increased cardiac output due to digoxin results in diuresis and general amelioration of the disturbances characteristic of right (venous congestion, edema) and left (dyspnea, orthopnea, cardiac asthma) heart failure.

Digoxin, generally, is most effective in "low output" failure and less effective in "high output" (bronchopulmonary insufficiency, infection, hyperthyroidism) heart failure.

Digoxin should be continued after heart failure is abolished unless some known precipitating factor is corrected.

2. Atrial fibrillation: Atrial fibrillation, especially when the ventricular rate is elevated. Digoxin rapidly reduces ventricular rates and eliminates the pulse deficit. Palpitation, precordial distress or weakness are relieved and any concomitant congestive failure ameliorated. Digoxin should be continued in doses necessary to maintain the desired ventricular rate and other clinical effects.

3. Atrial flutter: Digoxin slows the heart and regular sinus rhythm may appear. Frequently the flutter is converted to atrial fibrillation with a slow ventricular rate. Stopping digoxin at this point may be followed by restoration of sinus rhythm, especially if the flutter was of the paroxysmal type. It is preferable, however, to continue digoxin if failure ensues or if atrial flutter is a frequent occurrence.

4. Paroxysmal atrial tachycardia: Oral digoxin may be used, especially if the condition is resistant to lesser measures. Depending on the urgency, a more rapid acting parenteral preparation may be preferable to initiate digitalization, although if heart failure has ensued or paroxysms recur frequently, digoxin should be maintained by oral administration.

Digoxin is not indicated in sinus tachycardia unless due to heart failure.

5. Cardiogenic shock: The drug is often employed, especially when the condition is accompanied by pulmonary edema. Digoxin seems to affect adversely shock due to septicemia from gram-negative bacteria.

CONTRAINDICATIONS: The presence of toxic effects (see ADVERSE REACTIONS section) induced by any digitalis preparation is a contraindication to all of the glycosides.

Allergy, though rare, does occur. It may not extend to all preparations, and another may be tried.

Ventricular fibrillation.

WARNINGS:

> Digitalis alone or with other drugs has been promoted for use in the treatment of obesity. This use of digoxin or other digitalis glycosides is unwarranted. Moreover, since they may cause potentially fatal arrhythmias or other adverse effects, the use of these drugs in the treatment of obesity is dangerous.

Many of the arrhythmias for which digoxin is advised closely resemble those reflecting digoxin intoxication. If the possibility of digoxin intoxication cannot be excluded, cardiac glycosides should be temporarily withheld if permitted by the clinical situation.

The patient with congestive heart failure may complain of nausea and vomiting. These symptoms may also be indications of digoxin intoxication. A clinical determination of the cause of these symptoms must be attempted before further drug administration.

Patients with renal insufficiency require smaller than usual doses of digoxin. Newborn infants display considerable variability in their tolerance to digoxin, depending on their degree of maturity.

Premature and immature infants are particularly sensitive, and dosage must be reduced and digitalization should be even more individualized and cautiously approached than in more mature infants. Impaired renal function must also be carefully taken into consideration.

Congestive heart failure accompanying acute glomerulonephritis requires extreme care in digitalization. A relatively low total dose administered in divided doses and concomitant use of antihypertensive drugs has been recommended. ECG monitoring is essential. Digoxin should be discontinued as soon as possible.

Patients with idiopathic hypertrophic subaortic stenosis must be managed extremely carefully. Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Patients with rheumatic carditis, especially when severe, are unusually sensitive to digoxin and prone to disturbances of rhythm. If heart failure develops, digitalization may be initiated with relatively low doses; then it can be cautiously increased until a beneficial effect is obtained. If a therapeutic trial does not result in improvement, the drug should be considered ineffective and be discontinued.

Note: Digitalis glycosides are an important cause of accidental poisoning in children.

PRECAUTIONS: Atrial arrhythmias associated with hypermetabolic states are particularly resistant to digoxin treatment. Care must be taken to avoid digoxin toxicity if digoxin is used to help the arrhythmia.

Digoxin is not indicated for the treatment of ventricular tachycardia unless congestive heart failure supervenes after a protracted episode not itself due to digoxin.

Potassium depletion sensitizes the myocardium to digoxin and toxicity may develop even with usual dosage. Hypokalemia may also alter the rate of onset and intensity of the positive inotropic effect of digoxin. Therefore, it is desirable to maintain normal serum potassium levels in patients being treated with digoxin.

Potassium wastage may result from diuretic or corticosteroid therapy, hemodialysis, and from suction of gastrointestinal secretions. It may accompany malnutrition, diarrhea, prolonged vomiting, old age, and long-standing congestive heart failure. In general, rapid changes in serum potassium or other electrolytes are to be avoided, and intravenous treatment with potassium should be reserved only for special circumstances as described below (see TREATMENT OF ARRHYTHMIAS PRODUCED BY OVERDOSAGES section).

Patients with acute myocardial infarction, severe pulmonary disease, or far advanced heart failure may be more sensitive to digoxin and more prone to disturbances of rhythm.

Calcium affects contractility and excitability of the heart in a manner similar to that of digoxin. Calcium may produce serious arrhythmias in digitalized patients.

In myxedema, the digoxin requirements are less because excretion rate is decreased and blood levels are significantly higher.

In incomplete A-V block, especially in patients subject to Stokes-Adams attacks, advanced or complete heart block may develop if digoxin is given. Heart failure in these patients can usually be controlled by other measures and by increasing the heart rate.

Patients with chronic constrictive pericarditis may respond unfavorably to digoxin.

Patients with idiopathic hypertrophic subaortic stenosis must be managed extremely carefully. Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Renal insufficiency delays the excretion of digoxin and dosage must be adjusted accordingly in patients with renal disease. Note: This applies also to potassium administration should it become necessary.

Electrical conversion of arrhythmias may require reduction of digoxin dosage.

Dosage must be carefully titrated and differences in the bioavailability of parenteral preparations, elixirs, and tablets should be taken into account when switching patients from one preparation to another.

Electrocardiographic monitoring may be necessary to avoid intoxication.

Premonitory signs of toxicity in the newborn are undue slowing of the sinus rate, sinoatrial arrest, and prolongation of PR interval.

ADVERSE REACTIONS:
Gynecomastia: Uncommon.

Overdose or toxic effects in adults:
Gastrointestinal: Anorexia, nausea, vomiting, diarrhea are the most common early symptoms of overdosages in the adult (but rarely conspicuous in infants). Uncontrolled heart failure may also produce such symptoms.

Central nervous system: Visual disturbances (blurred vision, yellow vision), headache, weakness, apathy.

Cardiac disturbances (arrhythmias): Ventricular premature beats are the most common, except in infants and young children. Paroxysmal and nonparoxysmal nodal rhythms, atrioventricular (interference) dissociation and paroxysmal atrial tachycardia (PAT with block are also common arrhythmias due to digoxin overdosage.

Conduction disturbances: Excessive slowing of the pulse is a clinical sign of digoxin overdosage. Atrioventricular block of increasing degree may proceed to complete heart block. Note: The electrocardiogram is fundamental in determining the presence and nature of these cardiac toxic disturbances. Digoxin may also induce other changes (as of the ST segment), but these provide no measure of the degree of digitalization.

Overdose or toxic effects in children:
Toxic signs differ from the adult in a number of respects. Cardiac arrhythmias are the more reliable and frequent signs of toxicity.

Vomiting and diarrhea, neurologic and visual disturbances are rare as initial signs.

Premature ventricular systoles are rarely seen; nodal and atrial systoles are more frequent.

Atrial arrhythmias, atrial ectopic rhythms, and paroxysmal atrial tachycardia with A-V block particularly are more common manifestations of toxicity in children.

Ventricular arrhythmias are rare.

TREATMENT OF ARRHYTHMIAS PRODUCED BY OVERDOSAGE: Digoxin should be discontinued until all signs of toxicity are abolished. Discontinuation may be all that is necessary if toxic manifestations are not severe and appear after the time for peak effect of the drug.

Potassium salts are commonly used. Potassium chloride in divided oral doses totaling 4-6 grams for adults (see PEDIATRIC INFORMATION section for pediatric dosage) may be given provided renal function is adequate.

When correction of the arrhythmia is urgent and the serum potassium level is low or normal, potassium should be administered intravenously in a solution of 5 percent dextrose in water. A total of 40-100 milliequivalents (30 milliequivalents per 500 milliliters) is given at the rate of 20 milliequivalents per hour unless limited by pain due to local irritation.

Additional amounts may be given if the arrhythmia is uncontrolled and the potassium well tolerated.

Continuous electrocardiographic monitoring should be performed to watch for any evidence of potassium toxicity, e.g., peaking of T waves, and to observe the effect on the arrhythmia so that the infusion may be promptly stopped when the desired effect is achieved.

Caution: Potassium should not be used and may be dangerous for severe or complete heart block due to digoxin and not related to any tachycardia.

Other agents that have been approved for the treatment of digoxin intoxication include procainamide, lidocaine, and propranolol.

Pediatric Information: (See adult section for other recommendations for the treatment of arrhythmias produced by overdosages and for additional recommendations and cautions regarding the use of potassium.) Potassium preparations may be given orally in divided doses totaling 1-1.5 milliequivalents/kilogram (1 gram K contains 13.4 milliequivalents). When correction of the arrhythmia is urgent, approximately 0.5 milliequivalents/kilogram of potassium per hour may be given, with careful electrocardiographic monitoring, as a solution of 20 milliequivalents or less for 500 milliliters in 5 percent dextrose in water. The total dose should generally not exceed 2 milliequivalents of potassium/kilogram.

DOSAGE AND ADMINISTRATION: Oral digoxin is administered slowly or rapidly as required until the desired therapeutic effect is obtained without symptoms of overdosage. The amount can be predicted approximately from the lean body mass of the patient with allowances made for excretion during the time taken to induce digitalization.

Subsequent maintenance dosage is also determined tentatively by the amount necessary to sustain the desired therapeutic effect.

Recommended dosages are practical average figures that may require considerable modification as dictated by individual sensitivity or associated conditions. Diminished renal function is the most important factor requiring modification of recommended or average doses. (See WARNINGS and PRECAUTIONS sections.)

The average amount of digoxin that patients must accumulate to be digitalized with digoxin tablets is 1.0-1.5 milligrams. Digitalization may be accomplished by any of several approaches that vary in dosage and frequency of administration, but reach the same endpoint in terms of total amount accumulated.

In previously undigitalized patients, a single loading dose of 0.5-0.75 milligram orally usually produces a detectable effect in 1-2 hours that becomes maximal in 6-8 hours. Additional doses of 0.25-0.5 milligram may be given cautiously at 6-8 hour intervals to full digitalization.

In previously undigitalized patients, institution of daily maintenance therapy (0.125-0.5 milligram, see next paragraph) without a loading dose results in development of steady-state plateau concentrations in about 7 days in patients with normal renal function.

The average daily oral maintenance dose is 0.125-0.5 milligram, usually 0.25 milligram. In the elderly patient, 0.125-0.25 milligram should be considered the average maintenance dose.

In patients with renal impairment, digoxin excretion is impaired and serum half-life is prolonged. Digitalizing and maintenance doses are lower than those recommended for patients with normal renal functions. Signs of digoxin toxicity develop sooner in patients with renal impairment, and it takes longer for toxic signs and symptoms to disappear. Because of the prolonged half-life, a longer period of time is required to achieve an initial or new steady-state plateau in patients with renal impairment than in patients with normal renal function.

It cannot be overemphasized that the values given are averages and substantial individual variation can be expected.

Children: Digitalization must be individualized. Generally, premature and immature infants are particularly sensitive, requiring reduced dosage that must be determined by careful titration.

Oral Dosage. Beyond the immediate newborn period, children require proportionally greater doses than adults on the basis of body weight or surface area. The recommended oral digitalizing dosages in children with normal renal function are:

Newborn infants (normal), up to 1 month, require 40-60 micrograms (mcg)/kilogram.
Infants, 1 month to 2 years, require approximately 60-80 micrograms (mcg)/kilogram.
Children, 2 years to 10 years, require 40-60 micrograms (mcg)/kilogram.
Children, over 10 years of age, require adult dosages in proportion to their body weight.
Maintenance therapy is 20-30 percent of the digitalizing dose administered each day.

Long term use of digoxin is indicated in almost all infants who have been digitalized for acute congestive heart failure unless the cause is transient. Many favor maintaining digoxin until at least 2 years of age in all infants with paroxysmal atrial tachycardia or in those who show either definite or latent failure.

Many children with severe inoperable congenital defects need digoxin throughout childhood and often for life.

Left Ventricular Ejection Fraction and First Third Ejection Fraction Early After Acute Myocardial Infarction: Value for Predicting Mortality and Morbidity

ALEXANDER BATTLER, MD*
ROBERT SLUTSKY, MD
JOEL KARLINER, MD, FACC
VICTOR FROELICHER, MD, FACC
WILLIAM ASHBURN, MD
JOHN ROSS Jr., MD, FACC

La Jolla, California

In 102 patients with acute myocardial infarction total ejection fraction was measured 1 to 4 days after hospital admission with simultaneous measurement of first third ejection fraction, using first pass radionuclide angiography, in 44. Ejection fraction was reduced (<0.52) in 71 patients (70 percent) and first third ejection fraction was depressed (<0.25) in all 44 patients with this measurement. Among 98 patients followed up for 30 days, the admission ejection fraction was normal in 30 (31 percent, group A) and reduced in 68 (69 percent, group B). Mortality was similar in groups A and B (10 versus 9 percent) at 30 days but at 1 year was greater in group B (24 versus 10 percent); between 1 month and 1 year there were no further deaths in group A. First third ejection fraction was <0.17 in all 9 of the 44 patients with this determination who died within the 1st year; in 2 of the 9 total ejection fraction was >0.52. Nine of 21 patients (43 percent) with a first third ejection fraction value of <0.17 and 0 of 23 with a value of ≥0.17 died within the 1st year (p <0.005). Eighty-seven patients were followed up for 2 to 18 months (mean 11). The incidence of angina pectoris was similar in groups A (13 of 27, 48 percent) and B (27 of 60, 45 percent). Congestive heart failure occurred in 30 patients (50 percent) in group B and in only 4 (15 percent) in group A. At the end of the follow-up period, 46 of 66 patients (70 percent) in group B and 7 of 30 (23 percent) in group A had died or had congestive heart failure (p <0.05).

Thus, relatively early after admission for acute myocardial infarction total ejection fraction can fail to show left ventricular dysfunction in one third of patients, whereas the first third ejection fraction appears to be highly sensitive for detecting depressed left ventricular function. A total ejection fraction of <0.52 predicted a significantly increased combined morbidity from congestive heart failure and mortality during the 1st year after infarction, and a first third ejection fraction of <0.17 also predicted increased mortality during that period.

Depression of left ventricular function is an important factor in the prognosis of patients with chronic coronary artery disease.[1,2] A depressed

left ventricular ejection fraction measured with radionuclide angiography early after acute myocardial infarction[3–5] or on hospital discharge[6] is associated with increased mortality and morbidity from congestive heart failure during the subsequent year. Recently we[7,8] suggested that the first third ejection fraction derived from first pass radionuclide angiography is more sensitive than total ejection fraction for assessing left ventricular function in patients with chronic coronary heart disease and is as sensitive as the radionuclide angiographic stress test for identifying the presence of coronary artery disease. Accordingly, in this study we assessed further the early and late prognostic value of the total ejection fraction measured relatively early after admission for acute myocardial infarction and, in selected patients, compared it with the first third ejection fraction obtained with the first pass radionuclide angiographic method.

Methods

Patients: One hundred two patients with acute myocardial infarction admitted to the Research Unit of the University of California, San Diego Medical Center who had first pass radionuclide angiography within 4 days of admission constitute the study group. In 60 of the 102 patients the first pass radionuclide angiographic study was performed within the 1st day of admission, in 35 on the 2nd day, in 5 on the 3rd day and in 2 on the 4th day after admission. Seventy-nine patients were men and 23 were women; their mean age was 59 years (range 32 to 92).

The diagnosis of acute infarction was made when at least two of the following criteria were present: (1) a history of prolonged chest pain typical of infarction; (2) the evolution of electrocardiographic changes of acute infarction; (3) characteristic serial elevations of serum enzymes (creatine kinase, glutamic oxaloacetic transaminase, lactic dehydrogenase). Twenty-one patients had a previous myocardial infarction. In 44 patients the infarct was anterior by electrocardiographic criteria; in 41 it was inferior or posterior, and in 17 patients it was subendocardial. Numerous admission variables such as previous myocardial infarction, chronic obstructive pulmonary disease, a ventricular gallop, basilar rales, supraventricular tachycardia, sinus tachycardia, ventricular fibrillation, systolic and diastolic blood pressure, third degree atrioventricular (A-V) block, clinical class and localization of myocardial infarction were related to the initial ejection fraction determinations, and statistical significance was then determined using an analysis of variance.

Ninety-eight patients (excluding four patients who died from noncardiac causes) were followed up for 30 days (early death) and 12 months (late death) after the acute infarction. The cause of death was determined from the clinical diagnosis before death, the postmortem report, or both. For morbidity studies, 87 patients who survived the 1st month after acute infarction (excluding 1 patient lost to follow-up) were followed up 2 to 18 months (mean 11 months). Angina pectoris was diagnosed from the clinical history and congestive heart failure from the clinical history (shortness of breath during exertion, orthopnea), physical examination (ventricular gallop, basilar rales) and chest X-ray film (vascular redistribution or Kerley B lines).

Ejection fraction and first third ejection fraction: In 44 of the 102 patients, it was also possible to determine simultaneously the first third ejection fraction with the first pass radionuclide angiographic method, using the same raw data employed for calculating the total ejection fraction. In the remaining patients, tapes with raw data were no longer available for retrospective analysis of the first third ejection fraction. In the group of 44 patients, the relative values of the first third ejection fraction, total ejection fraction and clinical class of the Myocardial Infarction Research Units (MIRU) of the National Heart, Lung, and Blood Institute[9] for predicting 1 year mortality, congestive heart failure, recurrent myocardial infarction and angina pectoris were compared.

The first pass radionuclide angiographic technique and the calculations of left ventricular ejection fraction and the first third ejection fraction were performed as described previously.[7,10] In brief, 14 to 20 mCi of technetium-99m bound to human serum albumin, or technetium-99m in sodium pertechnetate was injected rapidly into a large peripheral vein. As the technetium bolus dose traveled through the heart, precordial activity was recorded in a 30° right anterior oblique projection using a mobile single crystal scintillation camera equipped with a general purpose parallel hole collimator and stored on a digital videotape. The data were transferred to a General Electric Med II computer system for processing. The total ejection fraction was calculated using a light pen-assigned region of interest surrounding the left ventricle to monitor counts at 0.04 second intervals during the transit of the radioactive agent through the cardiac chambers. Background corrections were made and a plot was produced showing the changes in count rate during approximately 10 to 15 heartbeats. The high frequency curve characterized by cyclic alterations in count rates between end-diastole and end-systole was used by the computer in the following formula for ejection fraction (EF):

$$\text{Total EF} = \frac{\text{End-diastolic counts} - \text{End-systolic counts}}{\text{End-diastolic counts}}.$$

To calculate the first third ejection fraction, the downward slopes of the high frequency time-activity curves were identified using the same beats to calculate both total and first third ejection fractions. End-diastole was chosen as the point with the highest number of counts just before ejection. End-systole was taken at a point with the smallest number of counts. The X-axis distance between these two points was defined as the left ventricular ejection time and was further divided into thirds. The ejection fraction during the first one third of systole (1/3 EF) was calculated manually using the following formula:

$$1/3\ \text{EF} = \frac{\text{End-diastolic counts} - \text{counts at 1/3 of systole}}{\text{End-diastolic counts}}.$$

As previously described, the correlation of first pass first third ejection fraction determined with the radionuclide method and with contrast ventriculography is very good ($r = 0.90$), and the intraobserver and interobserver variations are small (mean difference <0.025; range 0 to 0.05).[7]

Statistical analysis of the data: Analysis of variance, the chi square test and standard regression equations were used for statistical analysis. To compare further the sensitivity and specificity of total and first third ejection fractions for mortality, a receiver-operating characteristic analysis curve[11] was produced for both variables. This curve describes the compromises that can be made between sensitivity and specificity, the curve constituting a plot of sensitivity versus 1 minus specificity, with each point on the curve corresponding to these values for a specific threshold value. If the curve for a given predictor is consistently above that for another predictor it offers improved detection of risk because for any value of 1 minus specificity, the sensitivity is greater, whereas for any given sensitivity the corresponding value of 1 minus specificity

is less. All results are presented as the mean ± 1 standard deviation.

Informed written consent was obtained before each study.

Results

Admission findings: The relations between the total ejection fraction and initial clinical class and heart rate are presented in Figure 1. Total ejection fraction in the 47 patients in MIRU class I (no evidence of congestive heart failure) was 0.48 ± 0.10; it was 0.45 ± 0.18 in the 43 patients in class II (signs of mild left heart failure), 0.36 ± 1.0 in the 8 patients in class III (moderate left heart failure) and 0.39 ± 0.5 in the 3 patients in class IV (overt pulmonary edema and shock). Total ejection fraction was significantly reduced between classes I and III ($p < 0.02$). Only one patient in class III and none in class IV had a normal admission total ejection fraction (≥0.52). However, there were almost equal numbers of patients with normal or depressed left ventricular function in MIRU classes I or II. In the 30 patients with a heart rate greater than 100 beats/min, the ejection fraction averaged 0.40 ± 0.10; in those with a lower heart rate the mean total ejection fraction was 0.47 ± 0.10 ($p < 0.005$) (Fig. 1).

There were no significant differences in mean total ejection fraction among patients with different locations of myocardial infarction. Also, a history of previous myocardial infarction, chronic obstructive lung disease, the occurrence of a ventricular gallop, basilar rales, supraventricular tachycardia, sinus tachycardia, ventricular fibrillation, third degree A-V block, systolic and diastolic blood pressures during hospitalization did not correlate with the total ejection fraction.

Mortality: For follow-up studies, the patients were separated into two groups: group A, patients whose initial ejection fraction was normal (≥0.52) and group B, patients in whom it was depressed (<0.52). There was no improvement of the predictive value of the total ejection fraction for mortality when lower separation points were examined. Of the 98 patients, 30 were in group A (mean total ejection fraction 0.57 ± 0.04, range 0.52 to 0.70), and 68 were in group B (mean total ejection fraction 0.40 ± 0.07, range 0.23 to 0.51). There was no significant difference between these two groups with regard to mean age, site of infarction or previous myocardial infarction (Table I). The early mortality (less than 30 days) was the same for both groups (3 of 30 [10 percent] in group A; 6 of 68 [9 percent] in group B). However, the 1 year mortality rate was 2.4 times greater in group B (24 percent) than in group A (10 percent). Between 1 month and 1 year there were no further deaths in patients with a normal total ejection fraction, but 10 of the 62 patients (16 percent) in group B died during the follow-up study.

The causes of death in both groups are presented in Figure 2. When both early and late deaths are considered, the incidence of sudden death was similar in both groups (5 of 68 [7 percent] in group B; 2 of 30 [7 percent] in group A). The most frequent cause of death in group B was recurrent myocardial infarction (8 of 68, 12 per-

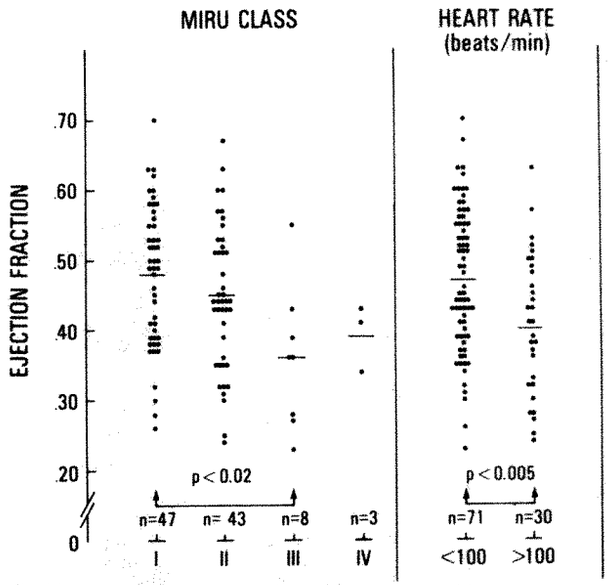

FIGURE 1. Relation between initial ejection fraction after acute myocardial infarction to initial Myocardial Infarction Research Unit (MIRU) clinical class (class I, no pulmonary venous congestion; II, slight pulmonary congestion; III, moderate pulmonary congestion; IV, overt pulmonary edema) and to heart rate. **Horizontal lines** represent the mean ejection fraction for each group. n = the number of patients in each group; p = probability.

TABLE I

Comparison Between Patients With a Normal (≥0.52, group A) and a Reduced (<0.52, group B) Initial Ejection Fraction

	EF ≥ 0.52 (group A, n = 30)	EF < 0.52 (group B, n = 68)
Age (yr)	59.5 (range 32–92)	58.4 (range 39–77)
EF	0.57 (range 0.52–0.70)	0.40 (range 0.23–0.52)
MI location (n)		
Anterior	12 (40%)	36 (44%)
Posteroinferior	12 (40%)	26 (41%)
Subendocardial	6 (20%)	10 (15%)
Previous MI (n)	7 (23%)	14 (21%)

EF = ejection fraction; MI = myocardial infarction; n = number of patients.

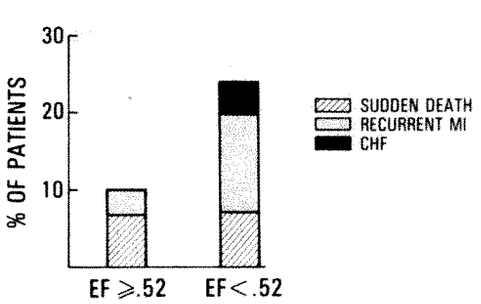

FIGURE 2. Mortality and causes of death within 1 year after acute myocardial infarction (MI) in the group of patients with an ejection fraction (EF) of ≥0.52, and the group with an ejection fraction of <0.52. CHF = congestive heart failure.

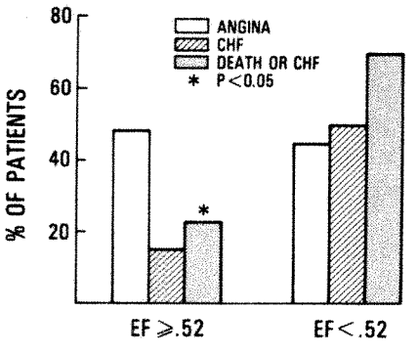

FIGURE 3. Relative morbidity from angina pectoris and congestive heart failure (CHF), as well as the combined mortality and morbidity from congestive heart failure within 1 year after acute myocardial infarction in the groups with a normal (≥0.52) and with a depressed (<0.52) initial ejection fraction (EF).

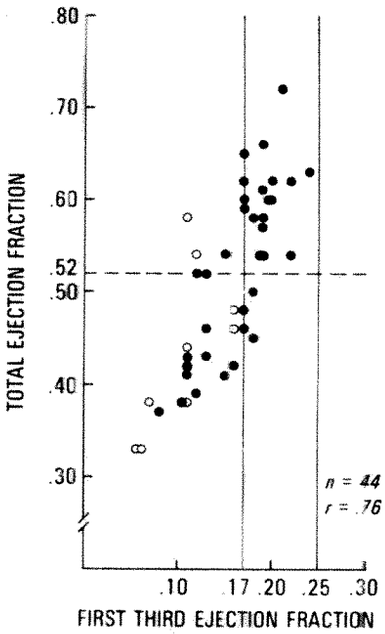

FIGURE 4. Correlation between the initial total and the initial first third ejection fractions in 44 patients with acute myocardial infarction. **Open circles** represent patients who died within the 1st year after infarction. The **dashed** line represents the lower normal range of total ejection fraction (0.52). **Vertical lines** represent the lower normal range of first third ejection fraction (0.25) and the value of first third ejection fraction (0.17) that separates patients with a high and a low 1 year mortality rate.

cent), compared with a 3 percent (1 of 30) incidence rate of this occurrence in group A. Three patients (4 percent) in group B and no patient in group A died of congestive heart failure.

Morbidity (Fig. 3): During the late follow-up period (2 to 18 months, mean 11 months) the incidence of angina pectoris was similar in both groups (27 of 60 [45 percent] in group B; 13 of 27 [48 percent] in group A). However, congestive heart failure occurred in 50 percent of patients in group B (30 of 60 patients) and in only 15 percent of patients in group A (4 of 27). At the end of the follow-up period, 70 percent of patients in group B (46 of 66) and only 23 percent of patients in group A (7 of 30) either were dead or had congestive heart failure ($p < 0.05$).

First third ejection fraction: In this group of 44 patients, the mean total ejection fraction was 0.52 ± 0.10, significantly higher than that in all 102 patients, 0.45 ± 0.11 ($p < 0.01$) and the mean first third ejection fraction was 0.16 ± 0.04. There was no significant difference between this subgroup of 44 patients and the total group of 102 patients with regard to mean age, site of myocardial infarction, previous myocardial infarction and other admission variables. On the basis of data obtained in 20 normal subjects, the mean normal first third ejection fraction was 0.29 ± 0.04 (range 0.25 to 0.36).[7] Figure 4 presents the correlation between the total and the first third ejection fractions. Twenty-three of the 44 patients (52 percent) had a normal total ejection fraction (≥0.52), whereas none had a normal first third ejection fraction (≥0.25). The best separation point for the first third ejection fraction in predicting 1 year mortality and morbidity was 0.17. In 21 patients the first third ejection fraction was <0.17, and in 23 it was ≥0.17. Nine of the 44 patients died in the subsequent year and each had a first third ejection fraction of <0.17, although 2 of the 9 had a normal total ejection fraction (0.54 and 0.58, respectively). The time-activity curve of one of these patients who had a normal initial total ejection fraction (0.58) and a reduced initial first third ejection fraction (0.11) is presented in Figure 5. Thus, 43 percent of patients (9 of 21) with a first third ejection fraction value of <0.17 and no patient with a value of ≥0.17 died in the year after acute myocardial infarction ($p < 0.005$). With use of a receiver-operating characteristic analysis, the curve for first third ejection fraction was always above the curve for total ejection fraction (Fig. 6), and therefore the former appeared to allow better detection of 1 year mortality in this group of patients. During the follow-up period, 7 of the remaining 12 patients with a first third ejection fraction of <0.17 near the time of admission had congestive heart failure; therefore, 76 percent of the patients with a first third ejection fraction of <0.17 either died or had congestive failure during the follow-up period.

MIRU class and ejection fraction (Table II): Comparison of the MIRU clinical class with total and first third ejection fractions in the 44 patients who had data for both variables indicates that the the MIRU class was superior for predicting the incidence of congestive heart failure within the 1st year after admission, whereas the first third ejection fraction was the only variable that significantly predicted 1 year mortality and recurrence of myocardial infarction.

Discussion

Radionuclide angiography has made it feasible to measure the ejection fraction non-invasively in patients with acute myocardial infarction during the early phase of hospitalization. In previous studies, such radionuclide angiographic ejection fraction determinations were used to predict prognosis of patients after acute myocardial infarction; however, small groups of patients were followed up for short periods (3 or 5 months),[3,4] or com-

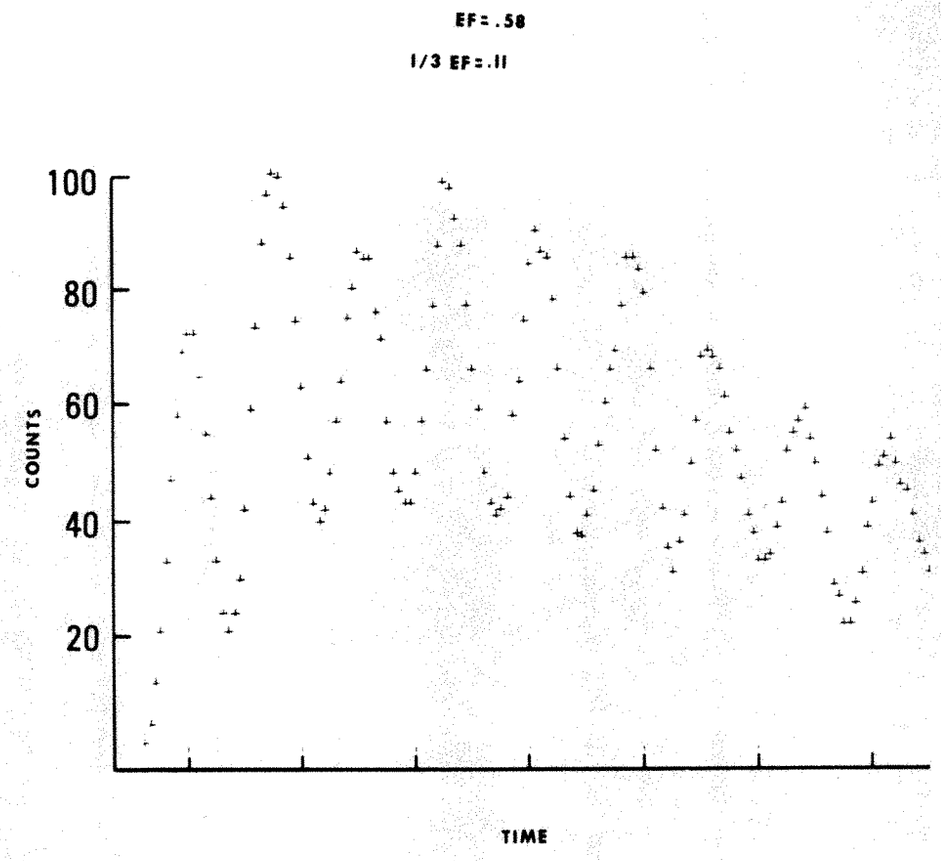

FIGURE 5. Typical time-activity (counts) curve after a single bolus injection of technetium-99m through the left ventricle. The patient, who died within the 1st year after myocardial infarction, had a normal (0.58) initial total ejection fraction (EF) and a reduced (0.11) initial first third ejection fraction (1/3 EF) as can be appreciated from the delayed ejection in this curve.

bined early and late ejection fraction determinations were used to predict mortality and morbidity.[5] It has been also suggested in these studies[3–5] that repeated measurements of ejection fraction might be more useful in predicting the prognosis of patients with acute myocardial infarction than the initial measurement alone, but such measurements are expensive and not always feasible. Therefore, it seemed important to assess the usefulness of ejection fraction determinations for

TABLE II

Morbidity and 1 Year Mortality in Relation to MIRU Clinical Class and Total and First Third Ejection Fractions (EF)

	Congestive Heart Failure (n)	Angina (n)	Recurrent Myocardial Infarction (n)	Death (n)
MIRU class				
I (n = 22)	0	7	1	3
II (n = 20)	6	10	5	5
III (n = 2)	2*	0	1	1
Total EF				
≥0.52 (n = 24)	3	9	3	2
<0.52 (n = 20)	5	8	4	7
One third EF				
>0.17 (n = 23)	2	6	0	0
<0.17 (n = 21)	6	11	7†	9‡

*, †, ‡ p = <0.001, <0.02, <0.005, respectively.
n = number of patients.

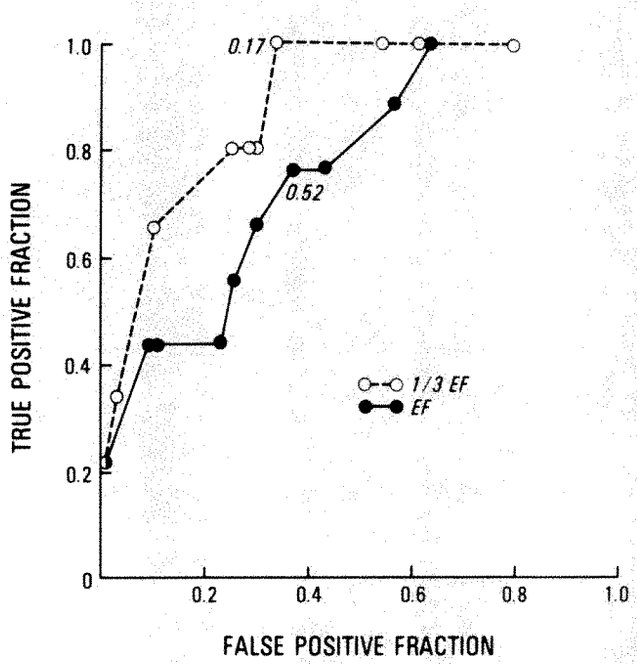

FIGURE 6. Receiver-operating characteristic curves to predict 1 year mortality in the 44 patients who had measurements of both total ejection fraction (EF) and first third ejection fraction (1/3 EF). Note that the 1/3 EF curve is always above the EF curve. See text for further details. False positive fraction (1 − specificity) = False positive/Actually negative. True positive fraction (same as sensitivity) = True positive/Actually positive.

predicting early and late mortality and morbidity when measured only once, relatively early after admission, in a group of patients followed up to a mean of 1 year after acute myocardial infarction.

Predictive value of total versus first third ejection fraction: In previous studies we[7,8] have shown that the ejection fraction measured in early systole is more sensitive than total ejection fraction for detecting left ventricular dysfunction.[7,8] In the present study, although the mean ejection fraction in all 102 patients was low (0.45 ± 0.11), 30 percent of the patients had a normal initial ejection fraction 1 to 4 days after the acute infarction and 10 percent of these patients died during the follow-up period; also, 1 year mortality in the group with a total ejection fraction of <0.52 did not differ statistically from the mortality in the group with an ejection fraction of ≥0.52, although it was higher. Within a subgroup of 44 patients (in which total ejection fraction was significantly higher 0.52 ± 0.10), each patient had a first third ejection fraction below normal. However, when the latter was <0.17, all patients who died were detected and 1 year mortality was significantly higher than when first third ejection fraction exceeded 0.17; in two of the patients who died within 1 year, the total ejection fraction was normal. The predictive value of 1 year mortality for total ejection fraction did not improve when lower total ejection fraction separation points were examined. Thus, it appears that the first third ejection fraction may provide a more sensitive definition of left ventricular dysfunction and constitute a better predictor of 1 year mortality than the total ejection fraction, although confirmation in a larger sample of patients is desirable.

Potential explanations for the better prediction of left ventricular function by early systolic ejection fraction rather than total ejection fraction during acute myocardial infarction include the possibilities that (1) abnormal aortic compliance in patients with atherosclerosis could cause depression of cardiac ejection rate early in systole,[12] and (2) partially damaged regions of the left ventricle fail to produce enough shortening early in systole when wall stress is relatively high, whereas shortening in these regions may occur late in systole as wall tension falls.

It was found that when left heart failure was absent or mild early after admission, the total ejection fraction could be either normal or depressed. It is possible that in some patients the presence of mitral regurgitation served to maintain the total ejection fraction within the normal range despite depressed left ventricular contractility.[13] With moderate to severe left heart failure, most patients had a depressed total ejection fraction. The small number of patients (three) in our study population with initial pulmonary edema and shock may be explained by the fact that patients in shock died relatively early after admission, before radionuclide angiography could be performed. This could also explain the lack of correlation between systolic blood pressure and ejection fraction determinations. Sinus tachycardia appeared to be associated with a significant decrease in ejection fraction, which might reflect increased sympathetic stimulation due to heart failure.

Implications: A total ejection fraction of <0.52 soon after admission with acute myocardial infarction is not associated with an increased rate of early mortality, sudden death or enhanced likelihood of angina during the subsequent year; however, during a 1 year follow-up period it presages increased mortality and morbidity due to recurrent myocardial infarction or congestive heart failure. An improved predictive value for 1 year mortality gained with use of the first third ejection fraction in a smaller subset of patients may offer the possibility of a more reliable predictor than total ejection fraction.

Regional and global left ventricular performance was noninvasively assessed with quantitative gated equilibrium radionuclide ventriculography in 43 patients an average of 40 hours after the onset of a first acute transmural myocardial infarction. In all 16 patients with anterior infarction, regional ejection fraction, a quantitative measure of regional left ventricular performance, was uniformly depressed in the infarcted zone. In patients with inferior infarction the abnormalities of regional performance were less severe. Fourteen of 20 patients (70 percent) with inferior infarction had depressed performance in the infarcted zone. Function in noninfarcted zones was abnormal in only 6 of the 20 patients (30 percent) with inferior infarction, but it was abnormal in 11 of the 16 patients (69 percent) with anterior infarction, particularly in those with severe pump failure. As a consequence, global left ventricular ejection fraction was significantly lower in patients with anterior than in those with inferior infarction (mean ± standard error of the mean 31 ± 3 percent versus 51 ± 3 percent, $p < 0.005$). Prognosis and clinical functional class were related to performance not only in infarcted zones, but also in noninfarcted zones as assessed with electrocardiography.

It is concluded that depressed function in apparently noninfarcted left ventricular zones contributes significantly to left ventricular dysfunction after acute myocardial infarction, particularly in patients with anterior infarction.

One of the most predictable events after an acute myocardial infarction is an abnormality of left ventricular systolic performance.[1] The pioneering work of Tennant and Wiggers[2] in 1935 demonstrated that interruption of the blood supply to a region of canine myocardium was promptly followed by cyanosis in the region, and subsequently by overt systolic bulging.

Several studies[3–6] have demonstrated the utility of radionuclide ventriculography in assessing sequential changes in global left ventricular function after myocardial infarction. However, quantitative changes in *segmental* left ventricular performance after infarction in human subjects have not been widely studied with noninvasive methods. We[7,8] have developed a reproducible and reliable technique utilizing the gated radionuclide ventriculogram to assess quantitatively regional left ventricular performance. In the present study, we applied this technique to assess the regional performance of infarcted and noninfarcted left ventricular segments after acute transmural myocardial infarction in human subjects.

Methods

Patients

Forty-three patients, 29 men and 14 women, admitted to the coronary care unit of the Peter Bent Brigham Hospital with well documented transmural myocardial infarction were studied with gated radionuclide ventriculography

From the Departments of Medicine and Radiology, Peter Bent Brigham Hospital and Harvard Medical School, Boston, Massachusetts. This study was supported in part by Grants HL 07049, HL 20895, HL 17739 and HL 24241 from the U.S. Public Health Service, Bethesda, Maryland. Manuscript received July 31, 1979; revised manuscript received November 2, 1979, accepted November 5, 1979.

* Recipient of a Young Investigator Research Grant from the National Heart, Lung, and Blood Institute, Bethesda, Maryland.

an average of 40 hours (range 5 to 96) after the onset of chest pain. All patients were studied at the bedside in the coronary care unit, with use of a portable gamma scintillation camera. The average age of the patients was 59 years (range 33 to 83).

The diagnosis of myocardial infarction was based on the presence of all of the following criteria: (1) Chest pain consistent with myocardial ischemia lasting for more than 1 hour. (2) Elevation of the total serum creatine kinase level to 50 percent or more above the upper limit of normal in the first 3 days of hospitalization and a subsequent reduction. (3) Detection of the MB isoenzyme of creatine kinase with electrophoretic assay of the patient's serum. (4) Standard electrocardiographic criteria[9] consistent with the diagnosis of acute myocardial infarction. Transmural infarction was diagnosed when Q waves with a duration of 0.04 second or greater than 25 percent of the amplitude of the R wave in the same lead were present and were accompanied by transient S-T segment elevation and followed temporarily by T wave inversion.

Criteria for exclusion from this study included: (1) acute nontransmural myocardial infarction; (2) left bundle branch block or other electrocardiographic abnormality preventing identification of the apparent infarct location (as judged from the appearance of pathologic Q waves); and (3) significant valvular heart disease.

Patients were questioned about prior chest pain suggesting myocardial ischemia or infarction, and available records from prior hospitalization and visits to physicians were analyzed for evidence of previous myocardial infarction. Patients with historical or electrocardiographic evidence of prior myocardial infarction were excluded from the study.

Site of infarction: The location of the infarct, determined with use of accepted electrocardiographic criteria,[10-12] was characterized as anteroseptal, apical or inferoposterior. No patient had an infarct limited to the lateral region of the left ventricle. Pyrophosphate infarct scintigraphy confirmed electrocardiographic infarct site in all 15 patients who underwent the nuclear study. Similarly, the vectorcardiogram, obtained at the bedside in six patients, was in agreement with the electrocardiographic findings on infarct site in all six patients.

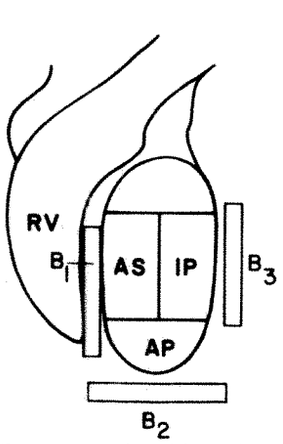

FIGURE 1. Schematic representation of the radionuclide ventriculogram in the modified left anterior oblique view. The right ventricle (RV) is shown, as are the three left ventricular regions (AP = apical; AS = anteroseptal; IP = inferoposterior). Three background correction regions (B_1, B_2, B_3) are generated by computer algorithm for regional background count determination.

Each left ventricular region (anteroseptal, apical, inferoposterior) was categorized according to the presence or absence of pathologic Q waves in corresponding electrocardiographic sites: Regions with Q waves were designated infarcted zones, and those without Q waves noninfarcted zones. Patients with an infarct localized to one anatomic zone of the left ventricle were classified as having an anterior infarction (including anteroseptal or apical infarction, or both) or an inferior infarction (including inferior or posterior infarction, or both).

Clinical functional class: Patients were categorized on admission into clinical functional classes based on the criteria of Killip and Kimball.[13] Twenty-two patients were in class I, 13 in class II, 3 in class III and 5 in class IV. All patients received standard coronary care, including nasally administered oxygen, sedatives, analgesic agents and antiarrhythmic drugs, as required. After the radionuclide study, two patients had recurrent chest pain associated with electrocardiographic changes that were believed to be compatible with infarct extension. Four patients (9 percent) died during hospitalization.

Radionuclide Data Acquisition and Analysis

Technique: Gated radionuclide ventriculograms were obtained with a portable gamma scintillation camera interfaced with a dedicated computer system. The technique used has been described in detail elsewhere.[7,8] Basically, it involved the in vivo labeling of red blood cells by the antecubital intravenous injection of unlabeled stannous pyrophosphate (5 mg of Pyrolite®, New England Nuclear Corporation) followed by injection of 15 to 25 mCi of technetium-99m as pertechnetate 15 to 20 minutes later.

Gated radionuclide ventriculograms were obtained utilizing an Anger camera with a high sensitivity 30° slant hole straight bore collimator (Engineering Dynamics Corporation, Lowell, Massachusetts).[14] Five minutes after injection of the radionuclide, the camera was positioned in the modified left anterior oblique projection (30° caudal tilt). Composite low count (400,000 counts) scintigrams were acquired until the camera obliquity demonstrating the greatest separation of the right and left ventricles was found (typically between 35° and 45° obliquity).

After the radionuclide had equilibrated with the intravascular space (5 minutes), 10 million counts (approximately 1,000 cardiac cycles) were acquired in matrix mode in 50 ms frames by a dedicated digital computer (PDP 11/34, Digital Equipment Corporation), using commercially available software (GAMMA 11). Only those photoevents falling within a 15 percent window centered on the photopeak of technetium-99m were recorded.

Global and regional ejection fractions: The end-diastolic left ventricular perimeter was manually traced with an electronic cursor. A time-activity histogram was generated from this region of interest, and end-diastolic and end-systolic

TABLE I

Normal Values of Regional Ejection Fraction[8]

Region	Regional Ejection Fraction (mean ± SD)
Anteroseptal	66 ± 13
Apical	85 ± 12
Inferoposterior	74 ± 16

frames were identified as those frames with the maximal and minimal counts, respectively, within the left ventricular perimeter. An automated computer algorithm that we[8] previously developed and validated was used to generate background correction regions, as well as to systematically divide the left ventricle into anteroseptal, apical and inferoposterior regions (Fig. 1). Ejection fraction was calculated for the entire left ventricle and for each of the three subregions with use of the formula

$$EF = \frac{ED - ES}{ED - B} \times 100\%,$$

where EF is ejection fraction, B is the background and ED and ES are the end-diastolic and end-systolic counts, respectively.

Thus, the change in counts in each left ventricular region was used to calculate a value, termed the regional ejection fraction, for that region. The range of normal values for regional ejection fraction has previously been established in our institution (Table I).[8] Because we have found that there is some variation in the normal regional ejection fraction in each of the three regions, we normalized the values in this study by dividing by the normal average value obtained for the respective region in a group of normal subjects, thus allowing direct comparison of function in one region with that in another. The lower limit of normal of the regional ejection fraction was defined as the mean obtained in the normal subjects minus 2 standard deviations. We[8] have previously reported the accuracy with which regional ejection fraction describes left ventricular asynergy.

Each left ventricular region (anteroseptal, apical inferoposterior) was identified as infarcted or noninfarcted on the basis of the electrocardiographic criteria described, and its segmental function was assessed with the regional ejection fraction. Because the values for regional ejection fraction were normalized for regional variation, changes in function in a given left ventricular region could be compared directly with changes in another region.

Statistical methods: Data are presented as the mean ± standard error of the mean. Comparisons between groups of patients were performed with a Student's *t* test. Significant differences were considered in those with a p value of <0.05.

Results

Twenty patients sustained an inferior myocardial infarction, and 16 patients an anterior infarction. The clinical course of 18 of the 20 patients with inferior infarction and 12 of the 16 patients with anterior infarction was uncomplicated, without clinical evidence of infarct extension or hospital mortality. In the remaining seven patients there was evidence of both anterior and inferior infarction. All four patients who did not survive hospitalization had an anterior infarction.

Identification of infarcted regions: Fifty-seven (85 percent) of 67 zones identified as infarcted with electrocardiographic criteria demonstrated an abnormal regional ejection fraction, whereas 21 (34 percent) of 62 electrocardiographically noninfarcted zones had a depressed regional ejection fraction. As might be anticipated, regional function was significantly more depressed in the infarcted than in the noninfarcted zones (Fig. 2).

Prognosis: The four patients who did not survive hospitalization had more severely depressed global left ventricular function than that of survivors (Fig. 3A). As a group, they demonstrated severe depression of function in the infarcted zone (Fig. 3B). In addition, function was abnormally depressed in the noninfarcted regions, whereas the mean value for function in these regions was normal, in survivors (Fig. 3C). Only one of these four patients underwent postmortem examination. Autopsy

demonstrated extensive infarction in the anteroseptal and apical regions, corresponding to a depressed regional ejection fraction (18 and 0 percent, respectively) in these regions at the time of radionuclide ventriculography.

Analysis of Killip classification showed similar trends. Because of the small number of patients in Killip classes III and IV (three and five patients, respectively), these classes were combined for purposes of analysis. There was a progressive deterioration in global ejection fraction with increasing Killip class (Fig. 4A), and regional ejection fraction in infarcted zones decreased as the Killip class increased from I to IV (Fig. 4B). Function in noninfarcted zones was well within the normal range for patients in Killip class I, but patients in Killip classes III and IV demonstrated significant depression of regional function (Fig. 4C).

Inferior infarction: Of the 20 patients with infarction limited to the inferior zone, 13 (65 percent) demonstrated depression of the global ejection fraction (Fig. 5A). Regional function in the infarcted zone was often, but not invariably, depressed; 14 of the 20 patients (70 percent) had a depressed regional ejection fraction (Fig. 5B). Function in the noninfarcted zone was usually normal. Only 6 of the 20 patients (30 percent) demonstrated a depressed regional ejection fraction in an uninvolved zone (Fig. 5C); the anteroseptal region was abnormal in 2 patients, the apical in 2, and both regions in 2.

Anterior infarction: Abnormalities in global and regional function were invariably more severe in patients with anterior than in those with inferior infarction (Fig. 5A). This was true in infarcted as well as noninfarcted zones (Fig. 5 B and C).

Global ejection fraction was depressed in all 16 patients with anterior infarction, and all 16 also demonstrated depressed regional ejection fraction in the infarcted zones. There was no significant difference in regional function in the infarcted zones in patients studied within 36 hours of infarction (regional ejection fraction 25 ± 6 percent) and those studied 37 to 96 hours after infarction (regional ejection fraction 34 ± 6 percent). Function in the noninfarcted regions was depressed in 11 of the 16 patients.

Discussion

This study demonstrates the feasibility of the noninvasive identification and assessment of the significance of regional performance of left ventricular segments after acute myocardial infarction in human beings. Regions with Q waves in corresponding electrocardiographic sites usually demonstrated depression of function after infarction; this was a universal finding in anterior infarction, and occurred somewhat less frequently after inferior infarction. Furthermore, regional left ventricular function was more severely depressed in the overtly involved segments of patients with ante-

FIGURE 4. rior infarction than of those with inferior infarction. In addition, electrocardiographically apparently uninvolved zones frequently demonstrated abnormal function. Global left ventricular function, as well as prognosis and clinical status, appeared to reflect the degree to which function was depressed in infarcted as well as more distant left ventricular segments.

Previous studies on asynergy of anterior versus inferior infarcts: Previous invasive investigations[15] have demonstrated that the hemodynamic consequences of acute myocardial infarction reflect, at least in part, the extent and degree of associated left ventricular asynergy. Anterior infarction is usually associated with higher filling pressures and larger left ventricular volumes than is inferior infarction,[16–18] and these hemodynamic abnormalities have been correlated with the degree of akinesia evident on contrast angiographic studies.[19] Anterior infarcts appear to be associated with quantitatively more myocardial necrosis than occurs with inferior infarcts, as assessed with serum creatine kinase analysis.[2] The degree of the resulting asynergy of the infarcted anterior segments is more marked than that of the infarcted inferior segments.[20] In the normal left ventricle, there is a greater degree of shortening of the anterior than of the posterior wall; thus, similar degrees of depression of function might be expected to result in more severe derangements after anterior infarction.[21,22] However, Miller et al.[23] investigated the mechanism by which anterior infarction leads to a greater depression of performance than is evident with inferior infarcts, and found that when the pattern of asynergy and the extent of the infarct were similar, the location of the infarct was unimportant. Our study has confirmed that quantitatively more depression of contractile function occurs with anterior than with inferior infarcts; whether anterior infarcts are geometrically larger remains unclear.

Regional function in noninfarcted ventricular zones: A somewhat unexpected finding of our study was the frequent demonstration of depressed function in ostensibly noninfarcted left ventricular regions, particularly in patients with anterior infarction. Because none of our patients had evidence of prior myocardial infarction, it is likely that the depressed regional function was not related to unrecognized prior infarction but reflected other factors (at least some of which have previously been studied). Mathes et al.[24] investigated the contractile state of noninfarcted right ventricular papillary muscle in cats subjected to left ventricular myocardial infarction and found moderate depression of function within the 1st week after infarction. Actively developed force and the response to provocative procedures to increase contractility did not return to normal until 6 weeks after infarction. The explanation for this observation remains unclear, especially in view of the enhanced function in noninfarcted segments demonstrated by others in animals[25] and human beings.[26] It has been suggested[24] that despite the apparent increase in function some workers have observed in these noninfarcted regions, these areas may be depending on the Frank-Starling mechanism and increased levels of circulating catecholamines to maintain function, whereas their basal contractile state is truly depressed. On the other hand, Corday, Meerbaum and co-workers[27,28] demonstrated in animal models that remote and apparently uninvolved myocardial regions may demonstrate not only depressed function, but also regional metabolic derangements indicating ischemia. Furthermore, microinfarcts have been observed histologically in regions remote from the site of experimental myocardial injury.[27] Depression of function in uninvolved regions has been attributed to regional ischemia,[28] catecholamine depletion[29] and left ventricular shape,[24] among other factors.

Whatever the explanation for this phenomenon, it is clear that left ventricular function depends on the integrity of function in the electrocardiographically noninfarcted regions. We have shown a close dependence of global function on regional function in noninfarcted as well as infarcted zones. One factor that appears to be responsible for improvement in left ventricular function in surviving myocardium is the development of hypertrophy.[25] Further investigation of the sequential changes in regional left ventricular performance after myocardial infarction may help clarify the factors that determine the extent to which surviving regions can compensate for the loss of infarcted myocardium.

Previous radionuclide studies of global left ventricular performance after myocardial infarction: Reduto et al.[6] sequentially studied right and left ventricular performance in 31 patients with uncomplicated transmural infarction. Inferior infarcts were associated with a greater depression in right ventricular ejection fraction than anterior infarcts, whereas left ventricular ejection fraction was lower with anterior infarcts (anterior 34 ± 3 percent; inferior 50 ± 3 percent). During the period of hospitalization, no significant change in global or regional performance was documented. However, patients with severe depression of function were excluded, and regional wall motion was qualitatively assessed. Rigo et al.[3] showed that global ejection fraction was depressed in patients with acute infarction, and it improved in all 14 patients who had clinical improvement; ejection fraction was unchanged in the 6 patients whose condition failed to improve or deteriorated. Determination of ejection fraction was made using conventional area-length measurements, as is done in contrast ventriculography, and regional function was assessed by analyzing the extent of akinetic segments. Schelbert et al.[5] found that 76 percent of patients demonstrated a depressed ejection fraction after infarction; improvement was seen in 55 percent of patients in the early follow-up period. Although Schelbert et al.[5] addressed the importance of the functional state of the residual noninfarcted myocardium, their analysis of wall motion was based not on the radionuclide angiocardiogram, but rather on a heart motion videotracker (radarkymograph). The latter instrument is not able to assess inferior left ventricular

wall motion, and its utility is limited by various extrapericardial processes including pulmonary fibrosis and edema.[30] Kostuk et al.[4] demonstrated that, although ejection fraction could not consistently be related to the site of the infarct, it correlated with the size of the infarct as determined from changes in serum enzyme activity. Serial studies showed improvement of global function in 55 percent of the patients; sequential changes in regional wall motion were not reported.

Correlation of electrocardiographic and ventriculographic localization of infarction: An abnormality of regional wall motion in the infarcted zone was noted in the majority of our patients. Electrocardiographic identification of the infarcted segment does not uniformly agree with histologic evidence of infarction.[10] However, previous studies[9,16,23,31] using contrast left ventriculography have demonstrated a close association between segmental left ventricular dysfunction and corresponding electrocardiographic localization of infarcted regions. The designation of infarcted segments in our study on the basis of the electrocardiogram is thus supported by these prior studies, which used a different technique.

The difficulty of deducing infarct extent from the standard electrocardiogram should be emphasized. Although the electrocardiogram can reliably distinguish between infarcts involving the anterior wall from those involving the posterior wall, it is less reliable in separating infarcts involving specific subdivisions of the anterior or posterior wall (anteroseptal, apical, anterolateral, for example).[32] The electrocardiogram frequently underestimates the extent of involvement of healed infarcts, and postmortem examination often demonstrates multiple sites of healed infarcts.[33] For these reasons, we limited our study to patients who had no clinical or other evidence of prior myocardial infarction. In addition, we compared patients who were grouped into two broad categories of infarct site (anterior and inferior) that can be reliably distinguished by the electrocardiogram.[32]

Clinical implications: Although the regional ejection fraction method provides a reproducible noninvasive measurement of quantitative segmental performance,[8] it does not directly indicate the relative size of infarcted or noninfarcted regions. However, it provides a means of assessing the evolutionary changes in regional performance after infarction. Quantitative evaluation of regional left ventricular wall motion after pharmacologic or surgical treatment in patients with myocardial infarction may provide useful information regarding the efficacy of a variety of interventions. Because our method of evaluating regional ventricular performance with use of the regional ejection fraction is based on changing count rates, a three dimensional perspective of changes in left ventricular blood volume is obtained. The technique is thus independent of geometric constraints, and is able to assess wall motion in regions of the ventricle that are not tangentially oriented to the detector. Previous studies from our institution[7,8] have demonstrated the reliability and accuracy of assessing the performance of multiple left ventricular regions from a single modified left anterior oblique gamma camera view.

Our findings in this study emphasize the frequent occurrence of dysfunction in left ventricular regions remote from infarcted zones, particularly after anterior infarction, and suggest that depression of mechanical performance in regions outside the ischemic zone may contribute to depressed cardiac performance after myocardial infarction.

EDWIN L. ALDERMAN, MD, FACC

Stanford, California

Left ventricular performance and segmental wall motion were studied sequentially in 12 patients during the 1st postoperative year after coronary arterial bypass graft surgery with use of computer-aided fluoroscopic analysis of radiopaque tantalum markers implanted into the left ventricular wall at operation. Measurements were made 1 week, 2 months and 1 year after operation. Ejection fraction decreased significantly early postoperatively (to 42 ± 3 percent [mean ± standard error of the mean]) but recovered to near preoperative values (55 ± 3 percent) at 2 months (49 ± 2 percent) and 1 year (51 ± 3 percent). Stroke volume increased from 51 ± 4 ml 1 week after operation to 70 ± 6 ml at 1 year; heart rate decreased from 91 ± 2 to 69 ± 4 beats/min during this interval. Both circumferential fiber shortening velocity and cardiac output were constant over the year. Total peripheral resistance was reduced in the early postoperative period. The data in the early postoperative period were consistent with those observed with an increase in heart rate alone, with only a small chronotropic augmentation of the myocardial contractile state. Total wall motion increased from 1 week to 2 months after operation primarily because of an increase in the extent of contraction of inferior wall segments, particularly in zones of previous infarction. Five of seven patients who had a preoperative myocardial infarction with hypokinesia of the infarcted region showed increased shortening in the region in the first 2 postoperative months. Four of six patients whose ejection fraction was less than 40 percent 1 week after operation had recurring angina; the six patients with a larger ejection fraction at this time had no recurrence.

Because resting left ventricular performance varies significantly during the 1st postoperative year, it is concluded that (1) results of evaluations made at widely differing times after operation should not be pooled in determining operative results; (2) studies made 2 or more months postoperatively are not subject to the rapidly changing values associated with the early postoperative period; (3) frequent sequential studies of left ventricular performance are required to evaluate operative outcome in an individual patient; and (4) wall motion in regions of previous infarction can be improved by coronary bypass graft surgery.

Correction of left ventricular dysfunction is a justifiable goal of coronary arterial bypass graft surgery because the state of left ventricular function is known to be an important factor in survival of patients with coronary artery disease.[1–3] There have been conflicting reports on the effect of coronary bypass surgery on left ventricular function. Some studies[4–9] have shown a failure of surgery to improve resting ventricular performance or segmental wall motion; others[10–14] have shown improvement of wall motion in regions of dysfunction both with and without improved overall ventricular performance.

One factor that could contribute to these mixed results is the timing of the postoperative evaluation.[15] Typically, left ventricular function has been assessed at a single time from 1 week to 1 year postoperatively, and results at different times have been pooled to evaluate operative outcome. Although Bourassa et al.[1] did make sequential evaluations of wall motion in 87 patients at 2 weeks and 1 year after operation, they did not report indexes of left ventricular performance.

In the present study we examined the postoperative time course of indexes of resting left ventricular performance and segmental wall motion in intact unanesthetized patients during the 1st year after coronary arterial bypass graft surgery. Most previous studies have utilized contrast angiography to assess left ventricular performance. This technique is limited by the effects of premedication and contrast injection and its invasive nature, which restricts its use in sequential determinations. In addition, Hugenholtz et al.[16] suggested that angiographic methods are only marginally useful in patients with coronary artery disease because truly comparable films are difficult to obtain and the data are internally inconsistent.

We avoided the difficulties of angiographic methods in the present study by using noninvasive serial fluoroscopic measurements of the dynamics of miniature tantalum markers implanted in the left ventricular myocardium at the time of operation. This method has the unique capability of allowing specific myocardial sites to be identified at each postoperative evaluation, assuring reproducibility in sequential determinations. Measurements of left ventricular dynamics in 12 resting supine patients were made at intervals of 1 week, 2 months and 1 year after operation in order to define the changes in left ventricular function occurring during this period.

Methods

Patient selection: Twelve patients who had coronary arterial bypass graft surgery during a 6 month period at Stanford University Medical Center, and who had technically adequate marker implantation and fluorographic studies 1 week, 2 months, and 1 year postoperatively were studied (Table I). The patients included nine men and three women, ranging in age from 39 to 64 years (mean 47) at operation. All patients had 70 percent or greater reduction in cross-sectional area of the left anterior descending coronary artery, seven had 50 percent or greater stenosis of the left circumflex coronary artery and eight had 50 percent or greater stenoses of the right coronary artery. Seven patients had a previous myocardial infarction and one patient had a minimally stenotic aortic valve. Medically unmanageable angina pectoris was the indication for surgery in all cases. Eleven patients had multiple grafts placed and all patients had at least one graft placed to a branch of the left coronary artery.

Procedures: At operation, after the establishment of cardiopulmonary bypass, the aorta was cross-clamped. Myocardial preservation was accomplished during the period of cardiac arrest by profound topical hypothermia with saline solution at 4° C and the distal anastomoses were completed. The aorta was unclamped and administration of cold saline solution discontinued. After 4 to 5 minutes of manual compression of the heart, electric defibrillation was effected. Proximal anastomoses were then carried out using a side-biting clamp on the aorta. Cardiopulmonary bypass was then discontinued.[17]

Informed consent for marker implantation during cardiac surgery and subsequent studies were obtained from all patients in accordance with the requirements of the Medical Committees on the Use of Human Subjects in Research at Stanford University and at the Palo Alto Medical Research Foundation. At the time of surgery, helical tantalum markers 0.85 mm in diameter and 1.5 mm long were implanted into the left ventricular myocardium, as previously described.[18] Each marker was implanted by threading the coil onto the point of an insertor that was used to implant the marker at a depth of 5 mm from the epicardial surface. Seven such markers were placed, three along the anterolateral wall, three along the inferior wall and one at the left ventricular apex to outline the left ventricle when it was viewed in the 30° right anterior oblique projection (Fig. 1). In addition, two metallic clips were attached to the adventitia of the ascending aorta, at the level of the aortic commissures, to provide reference points for the position of the aortic valve.

TABLE I
Study Patients

Case	Age (yr) & Sex	Preoperative Diagnosis	Coronary Arterial Lesions	Grafts Placed	Symptoms 1 Year After Operation
1	53F	Variant angina	95% LAD	LAD, diagonal	None
2	43M	Inferior MI, angina, aortic stenosis	100% LAD, 99% LCx, 95% RCA	LAD, RCA	None
3	64F	Unstable angina, inferior MI	80% LAD, 100% LCx, 100% RCA	LAD, LCx, marginal, RCA	None
4	39M	Inferior MI, angina	80% LAD, 80% LCx, 25% RCA	LAD, diagonal, LCx, RCA	Mild angina
5	59F	Inferior MI, angina	90% LAD, 45% LCx, 80% RCA	LAD, RCA	Angina
6	51M	Inferior & anteroseptal MI, angina	100% LAD, 50% LCx, 25% RCA	LCx, marginal	Angina
7	54M	Angina	80% LAD, 70% LCx, 90% RCA	LAD, diagonal, LCx, RCA	None
8	54M	Inferior MI, angina	85% LAD, 60% LCx, 100% RCA	LAD, LCx, RCA	None
9	45M	Unstable angina	95% LAD	LAD	None
10	48M	Unstable angina	100% LAD, 25% RCA	LAD, RCA	None
11	49M	Angina	85% LAD, 50% LCx, 80% RCA	LAD, RCA	None
12	44M	Inferior MI, angina	85% LAD, 90% LCx, 80% RCA	LAD, LCx, RCA	Angina

LAD = left anterior descending coronary artery; LCx = left circumflex coronary artery; MI = myocardial infarction; RCA = right coronary artery.

R_1, R_3, R_5 and R_2, R_4, R_6 are radii for measuring inferior and anterior wall shortening, respectively.

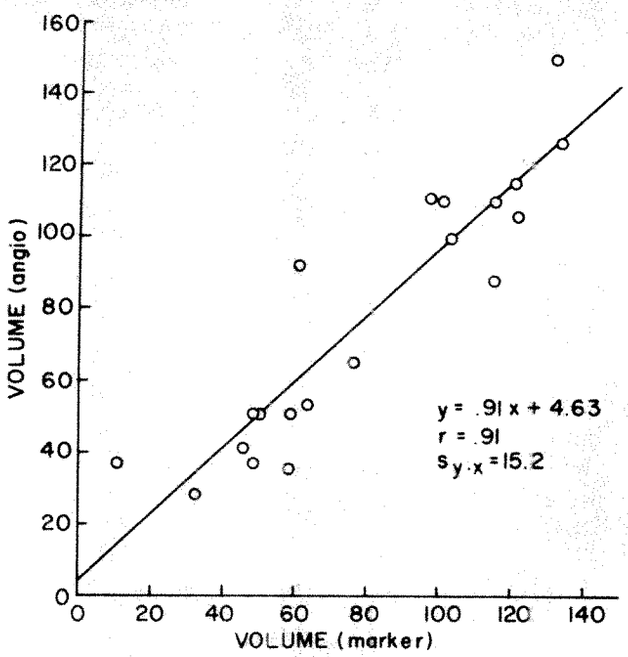

FIGURE 2. Scattergram of left vertricular volume measurements (in ml) from implanted mid wall markers (**abscissa**) and contrast ventriculography (**angio, ordinate**).

All patients had serum enzyme evaluations of serum lactic dehydrogenase, glutamic oxaloacetic transaminase and total creatine kinase (CK-MB isoenzyme in five cases) and electrocardiograms during the immediate (in-hospital) postoperative period and at subsequent follow-up studies. There were no electrocardiographic or serum enzyme changes indicative of myocardial infarction in the early postoperative period or during later follow-up. Eight of the 12 patients had complete relief of their anginal syndrome during the 1 year span of this postoperative study; in the remaining four patients, all of whom had multiple grafts, angina redeveloped 3 to 12 months postoperatively.

Postoperatively, fluoroscopic images from unsedated resting supine patients were recorded at 30 frames/s on a video disc recorder and replayed frame by frame on a video monitor. The X and Y coordinates of marker positions during three successive cardiac cycles were digitized by an operator using a light-pen and related temporally to the R wave of the analog electrocardiographic signal, which was recorded as a horizontal bar on the video image. Each measurement obtained from three successive cardiac cycles was then averaged and statistical differences between grouped data were assessed using Student's *t* test for paired observations.

Measurements of left ventricular function: *Left ventricular volumes at end-diastole and end-systole* were calculated from marker positions as described previously.[19] Volumes so obtained are highly correlated (r = 0.91) with those measured using contrast ventriculography (Fig. 2). Stroke volume and ejection fraction calculated from markers are also linearly correlated with the corresponding values measured from contrast ventriculography ($p < 0.01$).

Percent shortening of individual ventricular radii and circumferential fiber shortening velocity were also obtained from marker dynamics. Percent shortening of the anterior wall

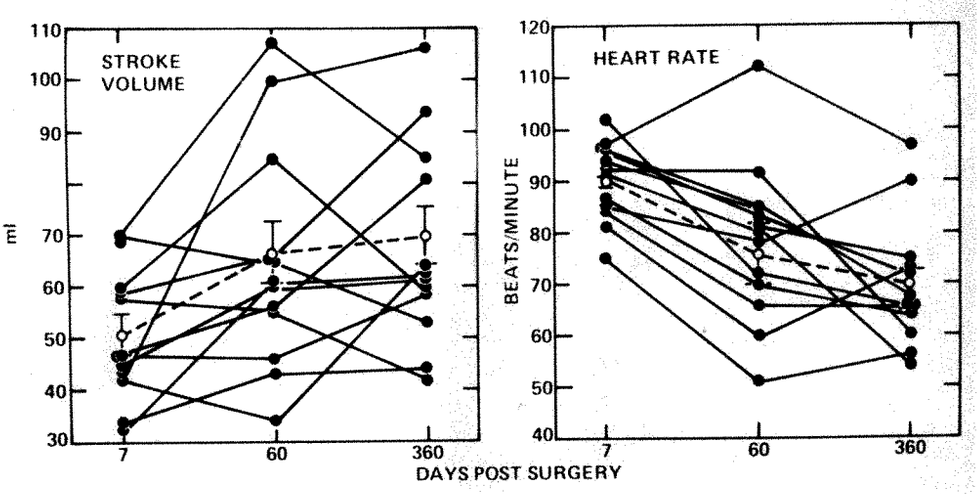

FIGURE 3. Serial measurements of stroke volume and heart rate for each patient are plotted against the number of days postoperatively. Mean values (**dashed line**) and standard errors are superimposed for each postoperative time.

(Fig. 1, radii R_2, R_4 and R_6) and inferior wall (Fig. 1, radii R_1, R_3, and R_5) were calculated together with total shortening, the arithmetic average of shortening of all individual radii. Mean error in measurement of mid wall shortening in this manner is 1.4 percent of end-diastolic length.[18] Velocity of circumferential fiber shortening was defined from the maximal ventricular diameter within 50 ms of the R wave peak and the diameter 167 ms later.[18] Velocities so defined are highly reproducible and sensitive to inotropic interventions.[20]

Reproducibility of the measurements (coefficient of variation in sequential beats) is 1.8 percent for end-diastolic volume, 1.0 percent for end-systolic volume, 4.0 percent for stroke volume, 2 percent for ejection fraction, 2.5 percent for velocity of circumferential fiber shortening, and 1 percent for total shortening.[21]

Results

Ventricular volumes and ejection fraction: Grouped data for all postoperative measurements are listed in Table II. Measurements of stroke volume, heart rate and ejection fraction for each patient are shown in Figures 3 and 4. Mean cardiac output was unchanged during the 1st postoperative year. Mean stroke volume (Fig. 3) increased 31.2 percent between the earliest postoperative study (1 week) and the 2 month postoperative study ($p < 0.05$). This increase in postoperative stroke volume was accompanied by a significant increase in mean ejection fraction (Fig. 4) from 42 percent 1 week postoperatively to 49 percent 2 months later ($p < 0.05$) and to 51 percent at 1 year. Ejection fraction 1 week postoperatively was significantly lower ($p < 0.01$) than the preoperative value (55 ± 3 percent [mean ± standard error of the mean]) but at 2 months and 1 year after operation was not significantly different from the preoperative value.

At the time of preoperative angiography mean systolic arterial pressure was 128 ± 5 mm Hg and mean diastolic pressure was 82 ± 3 mm Hg. Pressures were consistently lower in all patients 1 week postoperatively and increased steadily thereafter. These data, together with the unchanged cardiac output, demonstrate reduced total peripheral resistance in the early postoperative period.

Segmental wall motion: There was no significant change in circumferential fiber shortening velocity over the year. Total shortening increased 18.7 percent ($p < 0.05$) between 7 and 60 days postoperatively. When segmental inward excursion was analyzed separately for the anterior and inferior walls, it was noted that mean anterior wall shortening remained relatively constant over the entire postoperative year, whereas inferior wall motion increased significantly from 1 week to 2 months postoperatively. The increase in inferior wall shortening accounted for most of the observed increase in total shortening between the observations at 1 week and 2 months. The increase in mean inferior wall motion was

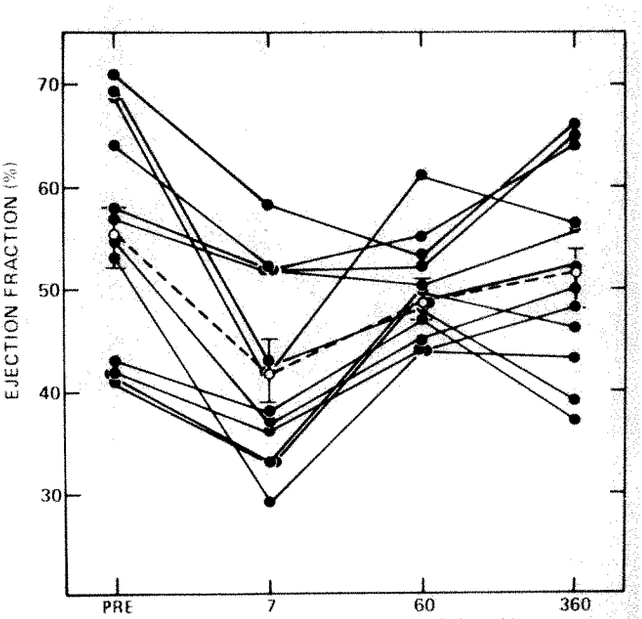

FIGURE 4. Individual measurements of ejection fraction for each patient plotted against the number of days postoperatively. Mean values (**dashed line**) and standard errors are shown for each postoperative time. Preoperative values were obtained from left ventriculography.

primarily due to a subgroup of five patients with a previous inferior infarction and evidence of hypokinesia of the posterior wall 1 week postoperatively. All five of these patients had bypass of a critically obstructed right coronary artery and four of those patients exhibited marked improvement in inferior segmental function between the 1 week and 2 month postoperative studies (Fig. 5). Anterior hypokinesia was present in three patients with a newly bypassed left anterior descending arterial lesion, one of whom had a prior anterior infarction. All showed considerable late postoperative improvement in segmental dynamics (Fig. 5). Of the seven patients who had preoperative myocardial infarction with hypokinesia of the infarcted region, five showed increased segmental shortening in that region over the first 2 postoperative months.

Discussion

Ejection fraction, left ventricular volumes and cardiac output: This study, which used a method permitting serial reproducible noninvasive measurements of left ventricular function, documents important changes in left ventricular performance over the first postoperative year. Ejection fraction decreased significantly in the early postoperative period with recovery to near preoperative values at 2 months and 1 year after operation. The unimproved ejection fraction found in the late postoperative period (relative to preoperative values) is in agreement with most previous studies.[4–9,22] Chatterjee et al.[11] and Rees et al.[12] found an improved ejection fraction in the early postoperative period. Because heart rate, stroke volume and cardiac output were all elevated in those studies it has been suggested that this was the result of an abnormally high sympathetic drive.[23]

In our study increases in ejection fraction in the postoperative period were brought about by increases in stroke volume. Changes in stroke volume paralleled those in end-diastolic volume, since end-systolic volume was constant. Other investigators[4–8,12] have also reported unchanged end-systolic volume from 5 weeks to 14 months after operation.

The most likely mechanism for the decreased end-diastolic volume observed in the early postoperative period is an abbreviated period of diastolic filling resulting from the tachycardia commonly observed after coronary arterial surgery.[4–10,12,22] Because the pericardium was widely opened at the time of surgery and not reapposed, it is not likely to have influenced end-diastolic volume. A change in left ventricular compliance due to the period of intraoperative ischemia is also unlikely to be a factor limiting end-diastolic volume because such changes tend to be resolved within 24 hours postoperatively[24] and our earliest measurements were of necessity made in ambulatory patients at 1 postoperative week.

The changes observed in the early postoperative period closely parallel the findings of our previous studies of the effect of increased heart rate on left ventricular performance in supine patients at rest, with concurrent

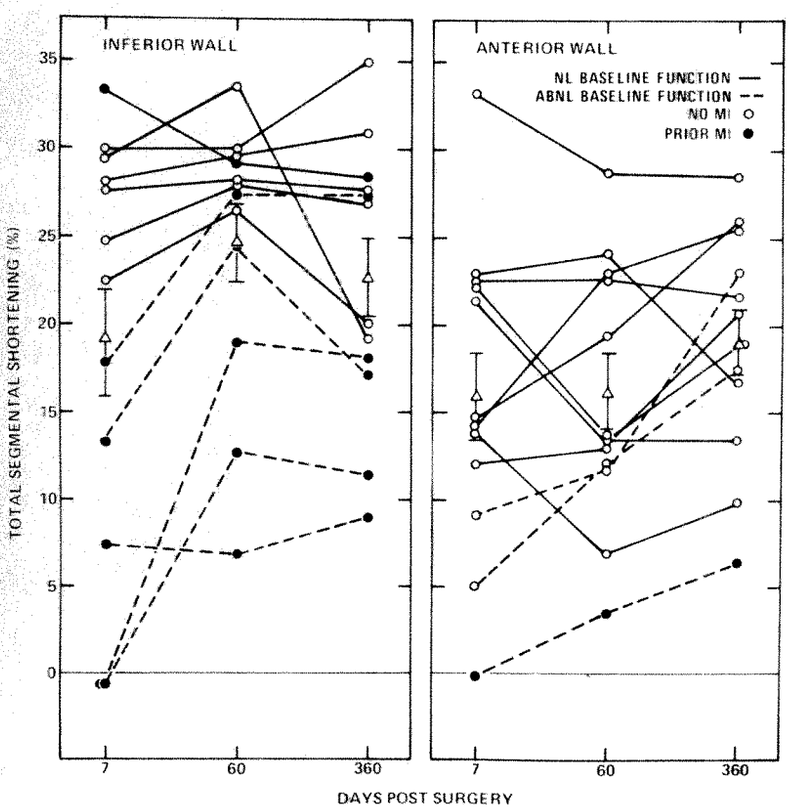

FIGURE 5. Serial postoperative changes in segmental shortening are shown separately for the inferior and anterior walls. **Open triangles** indicate mean values (± standard error) for all patients. **Open circles** indicate data from patients with no evidence of myocardial infarction. **Closed circles** indicate data from patients with prior electrocardiographically documented infarction in the distribution of the affected segments. **Dashed lines** show data from patients with abnormal segmental dynamics in the earliest postoperative study (1 week). In general, most segments that were abnormal in the study at 1 week showed significant improvement in later follow-up. ABNL = abnormal; MI = myocardial infarction; NL = normal.

decreases in end-diastolic volume, stroke volume, ejection fraction and blood pressure and constant values for cardiac output and velocity of circumferential fiber shortening.[25] Thus, the conditions we observed in the early postoperative period are consistent with those due to the observed increase in heart rate alone, with only a small chronotropic augmentation of the myocardial contractile state.[26] Although sympathetic tone is frequently elevated in the early postoperative period,[5,7,9,15,22] it is unlikely that circulating catecholamines were a dominant factor in our results, because the increased heart rate was matched by a decreased stroke volume that led to a constant cardiac output within the normal range. The mild tachycardia could be due to the baroreceptor reflex responding to the reduction in pressure that accompanied the decrease in peripheral resistance 1 week after operation. As peripheral resistance normalized over the year, blood pressure increased, with resolution of the tachycardia.

Left ventricular wall motion: The increase in overall segmental shortening was found to be due primarily to an increase in inferior wall shortening, with mean anterior wall shortening essentially unchanged over the year. Of the seven patients who had a preoperative myocardial infarction, five showed improved segmental shortening in the distribution of the graft to the infarcted area. This suggests that reperfusion of ischemic muscle in and around areas of prior infarction can improve regional contraction in those areas. Previous investigators have reported that more than half of wall segments with motion defects showed early postoperative improvement after coronary bypass surgery and that this frequently persisted,[1,27] but emphasized that regional improvement cannot be expected unless preoperative function is depressed.[22]

Postoperative angina: Four patients (33 percent) had recurrence of angina within the 1st postoperative year. This incidence rate is in close agreement with that of other reported series[22,28,29] in which angina returned in 27 to 29 percent of patients in the same period. Recurrence of angina in our study was not correlated with decreased ejection fraction at 1 year postoperatively. However, angina returned in four of the six patients whose ejection fraction was less than 40 percent 1 week after operation, whereas there was no recurrence of angina in the six patients whose ejection fraction was larger at this time.

Because our postoperative study was designed to be wholly noninvasive, no postoperative angiographic studies of graft patency were performed. Because the surgical technique is the same as that previously used[17] (in which 76 percent of grafts were patent 1 year after operation[29]) and because the incidence of angina in the 1st postoperative year corresponds to prior experience[22,28-30] and because mean ejection fraction at 1 year is not significantly different from the preoperative value,[22] we believe that most of the grafts in these patients are likely to be patent.

Implications of study: Our data show that resting left ventricular performance after coronary arterial bypass graft surgery varies significantly both in the individual patient and in the group during the 1st postoperative year. This finding suggests that (1) results of evaluations made at widely differing times after operation should not be pooled in determining operative result; (2) studies made two months or more postoperatively are not subject to the rapidly changing values associated with the early postoperative period; (3) frequent sequential studies of left ventricular performance are required to evaluate operative outcome in an individual patient; and (4) wall motion in regions of previous infarction can be improved by coronary arterial bypass graft surgery.

Combined Right and Left Ventricular Infarction: Pathogenesis and Clinicopathologic Correlations

NORMAN B. RATLIFF, MD
DONALD B. HACKEL, MD*

Durham, North Carolina
Minneapolis, Minnesota

An autopsy examination was made in 102 consecutive cases of fatal myocardial infarction that occurred in a coronary care unit. Thirty-five of the patients (34 percent) were found to have right ventricular infarction. All of the right ventricular infarcts were associated with transmural infarction of the posterior left ventricle or the interventricular septum, or both. The group with right ventricular infarction was compared with that without right ventricular infarction. Both groups had a predominant pattern of coronary arterial atherosclerosis consisting of severe stenosis of the proximal left anterior descending and proximal right coronary arteries with variable involvement of the left circumflex and left main coronary arteries. There was no significant difference between the two groups in severity or distribution of coronary arterial atherosclerosis. However, the group with right ventricular infarction had twice as many recent coronary arterial occlusions as did the group with left ventricular infarction and at least one recent coronary arterial lesion was present in 86 percent of those with right ventricular infarction, compared with only 30 percent of the group with left ventricular infarction. The majority of the acute coronary arterial lesions in both groups were thrombotic, but many intramural hemorrhages within atherosclerotic plaques were also found. In both groups the greatest number of recent coronary arterial occlusions was in the proximal right coronary artery, but the acute lesions were distributed throughout the coronary arterial tree.

Clinically significant right ventricular infarction complicating left ventricular infarction is being diagnosed and treated with increasing sophistication.[1–5] Although the incidence of right ventricular infarction remains uncertain, recent pathologic studies indicate that the lesion may be frequently associated with transmural infarction of the posterior wall of the left ventricle.[6–9] In one extensive pathologic study,[9] a right ventricular infarction was associated exclusively with transmural posteroseptal left ventricular infarction and occurred in 50 percent of the cases of transmural infarction of the interventricular septum. However, the reasons for the development of right ventricular infarction in only a fraction of the cases of transmural posteroseptal left ventricular infarction remain unknown. In this study, pathologic data are presented relating combined right and left ventricular infarction to the patterns and incidence of coronary arterial atherosclerosis, thrombosis and hemorrhage into atherosclerotic plaques. Possible implications of these relations in the pathogenesis of right ventricular infarction are discussed.

Methods

Criteria for right ventricular infarction: In this study, *right ventricular infarction* refers to combined right and left ventricular infarction and *left ventricular infarction* to infarction of the free wall of the left ventricle or interventricular septum, or both, without involvement of the right ventricle. The

criteria for the diagnosis of infarction of the right ventricle were necrosis, organization or fibrosis of the free wall of the right ventricle in the presence of atherosclerosis of the right coronary artery with at least 50 percent stenosis of its lumen. These changes had to extend more than 1 cm into the free wall of the right ventricle. Scattered small foci of necrosis, often seen after cardiogenic or hypovolemic shock, were not included as infarction of the right ventricle.[10,11]

Cases: All 102 patients in this report are consecutive patients who died after treatment for myocardial infarction in the coronary care unit at Duke University Medical Center and who were examined at autopsy; all were found at autopsy to have myocardial infarction. Thirty-five of the hearts had evidence of right ventricular infarction.

Heart preparation: The heart was weighed, photographed and X-rayed using a beryllium window X-ray unit and high resolution film. The orifices of the left and right coronary arteries were cannulated and injected with a colloidal suspension of micropaque and formalin in gelatin at a constant pressure of 100 mm Hg for 25 minutes. After the injection, the heart was again X-rayed in anteroposterior, lateral and oblique views. If necessary, the coronary arteries were then decalcified.

Coronary arteries: The coronary arteries were examined, using the radiographs as a guide, by multiple transverse cuts at intervals of 2 to 3 mm. The location and severity of atherosclerotic plaques, thrombi, hemorrhage into atherosclerotic plaques (intramural hemorrhage) and calcification were recorded. All major branches were examined and traced until they were too small to visualize. Major atherosclerotic lesions, thrombi and intramural hemorrhage were confirmed microscopically. The recorded locations were left main, proximal and distal left anterior descending, left circumflex, proximal and distal right and posterior descending coronary arteries. Anterolateral coronary arteries were recorded when they were present. Stenosis by atherosclerotic plaques was recorded as absent, less than 25 percent stenosis, 25 to 50 percent stenosis, 50 to 75 percent stenosis, stenosis greater than 75 percent but not complete occlusion, and complete occlusion. Thrombi and intramural hemorrhage were recorded as occlusive or nonocclusive. Calcification was recorded as absent, minimal or severe. Coronary dominance was determined by the artery that gave rise to the posterior descending coronary artery.

Myocardial infarcts: Four equally spaced transverse cuts were made across both ventricles and the interventricular septum. Both atria and all four valves were opened. Measurements of ventricular thickness and valve diameter were recorded. Infarcts as seen grossly were outlined on diagrams and confirmed microscopically. At least 16 histologic sections of the ventricles that were obtained from standardized areas were examined in each case. Routine staining was with hematoxylin-eosin, and additional sections were stained with phosphotungstic acid hematoxylin or Masson's trichrome stain. Large histologic sections encompassing a full cross section of both ventricles and the interventricular septum were stained with Masson's trichrome stain in each case. Because all of the right ventricular infarcts were transmural, their size was estimated in each case as the percentage of the circumference of the right ventricle that was infarcted. Left ventricular infarct size was measured in 20 consecutive cases as previously reported[12,13]; this series included 8 cases of right ventricular infarction. All infarcts and coronary arterial lesions were encoded on computer-compatible forms. The patterns of coronary artery disease were analyzed by discriminate and multivariate analysis on an IBM 360/75 computer.

Results

Patient groups: All of the 102 hearts contained infarcts of the left ventricle or interventricular septum, or both. Thirty-five of these hearts also contained right ventricular infarction, an incidence of 34 percent. These 35 cases constitute the right ventricular infarction group and the remaining 67 cases represent the left ventricular infarction group.

Myocardial pump failure, manifested by either cardiogenic shock or congestive heart failure, was the predominant clinical problem in both groups, with no significant difference in the incidence of pump failure or arrhythmias between the two groups (Table I).

Features of right ventricular infarction: All right ventricular infarctions were transmural and, with one exception, involved the posterior wall of the right ventricle with varying amounts extending to the lateral and anterior walls. All were associated with transmural posterior left ventricle infarction, and 31 were also associated with transmural infarction of the interventricular septum. Thirty of the right ventricular infarcts were contiguous with the associated left ventricular infarct.

Five right ventricular infarcts were separated from the left ventricular infarcts by normal myocardium. In four of these cases the normal myocardium was the posterior interventricular septum. In the remaining case, the right ventricular infarction involved only the lateral wall of the right ventricle. The right ventricular infarcts bore no discernible relation to the size of the left ventricular infarcts, except that they occurred only in the presence of transmural infarction of the posterior left ventricle. Left ventricular infarct size ranged from 8 to 72 percent of the left ventricle in the 20 cases in which it was measured. There was an excellent inverse correlation between left ventricular infarct size and cardiac index, and the patients with right ventricular infarction had a significantly higher right atrial pressure than those without right ventricular infarction.[12] However, reexamination of these data revealed no correlation between left ventricular infarct size and the presence or size of a right ventricular infarct. Both the largest (circumferential) and the smallest (subendocardial) left ventricular infarcts were not associated with right ventricular infarction.

In all 35 cases of right ventricular infarction the infarction of the right ventricle was acute. The acute infarct involved approximately 80 percent of the right ventricle in 2 cases in which there was clinical evidence of severe right ventricular dysfunction[1,2] (Fig. 1); it involved 25 to 50 percent of the ventricle in 10 cases and 10 to 25 percent in the remaining 23 cases. In addition, 11 of these cases contained healed (fibrotic) infarcts and 5 contained healing (organizing) infarcts of the right ventricle.

Coronary circulation: The coronary circulation was right dominant in 80 percent of the cases in both groups. The predominant pattern of coronary arterial atherosclerosis was stenosis of 75 percent or more of the lumen

TABLE I

Clinical Features*

	Cardiogenic Shock	Congestive Heart Failure	Atrioventricular Block	
			1st or 2nd Degree	3rd Degree
Right ventricular infarction	46% (16)	31% (11)	23% (8)	6% (2)
Left ventricular infarction	37% (25)	39% (26)	13% (9)	10% (7)

* The number of cases with each clinical feature is in parentheses. The differences are not statistically significant.

TABLE II

Coronary Arteries With 75 Percent or Greater Stenosis by Atherosclerosis*

	Artery		
	RCA	LAD	LCx
Right ventricular infarction	91% (32)	80% (28)	60% (21)
Left ventricular infarction	66% (44)	72% (48)	51% (34)

* The number of cases is in parentheses. The differences are not statistically significant.

LAD = left anterior descending artery; LCx = left circumflex artery; RCA = right coronary artery.

in the proximal left anterior descending and proximal right coronary arteries with variable involvement of the left circumflex and left main coronary arteries (Table II). There was no significant difference between the two groups in severity or distribution of coronary atherosclerosis or calcification, or in the anatomy of the coronary arteries as determined by use of the chi square and by multivariate and discriminate analysis.

There was a distinct difference between the two groups in the combined incidence of recent coronary arterial thrombosis and intramural hemorrhage. The number of patients with recent coronary arterial occlusions was significantly higher in the group with right ventricular infarction, and more patients in this group had an acute coronary arterial lesion. At least one recent coronary arterial lesion was found in 86 percent of the patients with right ventricular infarction cases but in only 30 percent of the patients with left ventricular infarction. Several patients had had more than one recent coronary arterial lesion and twice as many recent coronary arterial occlusions were present in the group with right ventricular as in the group with left ventricular infarction (Table III).

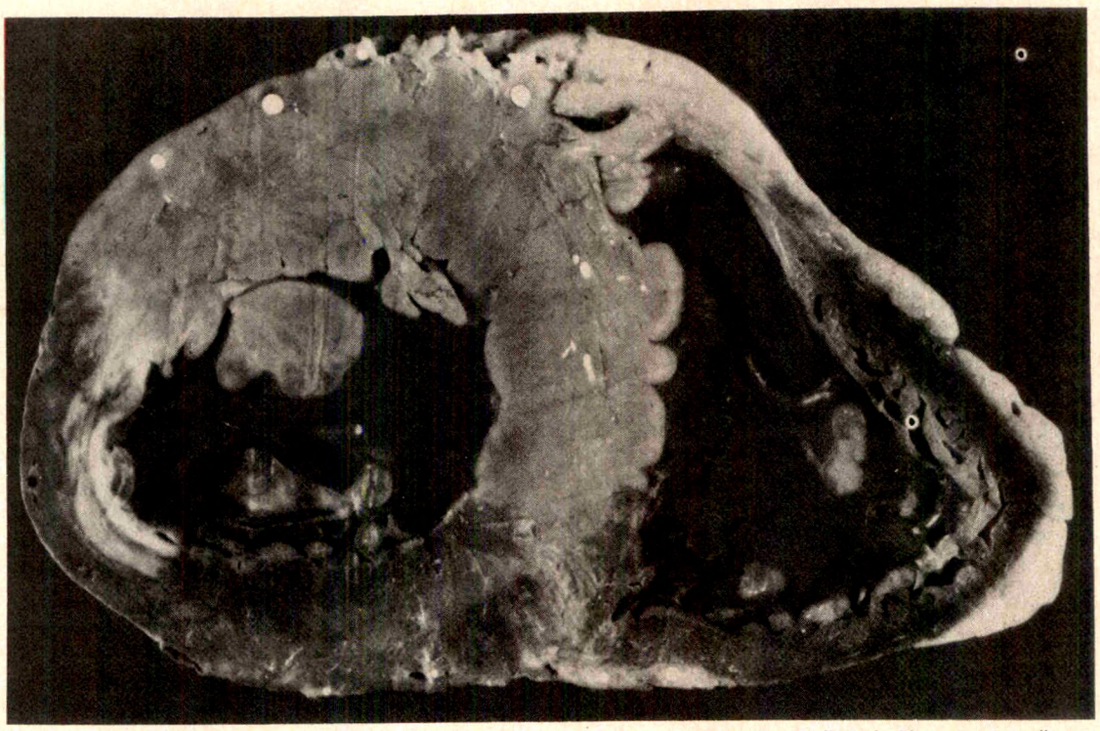

FIGURE 1. Cross section of the ventricles near the base of the heart. The coronary arteries have been injected with contrast medium and the heart has been fixed in formalin. Coronary arteries filled with white contrast medium can be seen along the epicardial surface of the anterior wall of the left ventricle and the anterior interventricular septum. Smaller arteries can be seen within the anterior half of the interventricular septum. A small old subendocardial infarct is visible as a white scar in the lateral wall of the left ventricle. An acute transmural infarct, which appears dark in the photograph, involves the lateral and posterior walls of the left ventricle and the posterior interventricular septum. The infarct is contiguous with an acute transmural infarct of the right ventricle, which involves its posterior wall, lateral wall and part of the anterior wall.

TABLE III

Acute Coronary Arterial Lesions*

	Cases (n)	Cases With an Acute Lesion† (n)	Acute Occlusions (n)‡	Nonocclusive Acute Lesions§
Right ventricular infarction	35	30	32	18
Left ventricular infarction	67	20	16	15

* Includes occlusive and nonocclusive coronary thrombi and hemorrhage into atherosclerotic plaques.
† $p < 0.01$.
‡ $p < 0.0001$. } $p < 0.0005$.
§ Not significant.
n = number.

The difference between the two groups with respect to the presence of an acute coronary arterial lesion was significant ($p < 0.01$) when the chi square with Yate's correction factor was used. The difference in the total number of acute coronary arterial occlusions was significant ($p < 0.0001$). When these two numbers (the difference in cases with an occlusion and the difference in total acute lesions) are combined into a 6×2 chi square with Yates' correction factor and 5 degrees of freedom, then $p < 0.0005$.

The distribution of acute coronary arterial lesions is shown in Table IV. Most of the acute occlusions and the acute lesions without occlusion were found in the right coronary artery in both groups. However, the acute lesions were distributed throughout the coronary arteries and there was no statistically significant difference in this distribution between the two groups. Of the acute occlusions 56 percent were thrombotic, 32 percent were secondary to intramural hemorrhage and 12 percent were a combination of thrombosis and intramural hemorrhage without any significant difference between the two groups. The significant difference between the groups with right and left ventricular infarction was the marked increase in acute lesions throughout the coronary arterial tree in the patients with right ventricular infarction.

TABLE IV

Distribution of Acute Coronary Arterial Lesions

	Acute Occlusion		Acute Lesions Without Occlusion	
	Right Ventricular Infarction	Left Ventricular Infarction	Right Ventricular Infarction	Left Ventricular Infarction
Proximal right coronary artery	11	7	5	10
Distal right coronary artery	7	3	0	1
Posterior descending coronary artery	1	1	1	1
Left main coronary artery	0	1	0	0
Left circumflex coronary artery	7	2	1	0
Proximal left anterior descending coronary artery	6	2	8	3
Distal left anterior descending coronary artery	0	0	3	0

Discussion

Incidence of right ventricular infarction: Patients who die in a coronary care unit are a select population, and this factor probably influenced the incidence of right ventricular infarction in our study. Other recent autopsy studies reported an incidence of right ventricular infarction of 43 percent in a coronary care unit population[7] and 14 percent in a more varied population.[9] The incidence of healed and healing right ventricular infarcts found in our study (16 percent) is similar to the overall incidence reported by Isner and Roberts,[9] whereas our incidence of acute right ventricular infarction associated with left ventricular infarction is similar to that reported in recent clinical studies using radionuclide imaging techniques.[3,4] The severity of right ventricular dysfunction in the two patients in our study with a very large right ventricular infarct supports the observations of Wackers et al.[3] that the size of the right ventricular infarct influences the severity of right ventricular dysfunction. The small number of very large right ventricular infarcts is also in accord with the low incidence of clinically significant right ventricular infarction reported by Lorell et al.[5]

Location: Isner and Roberts[9] reported right ventricular infarction exclusively as a complication of posterior left ventricular infarction, whereas Erhardt[7] observed it in 10 cases of anterior infarction. Our findings support those of Isner and Roberts, except that we did not find infarction of the interventricular septum in all cases of right ventricular infarction.

Pathogenesis: role of collateral blood flow: Right ventricular infarction without infarction of the left ventricle is rarely seen at autopsy and is usually associated with right ventricular hypertrophy and pulmonary arterial hypertension.[14,15] Furthermore, the transmural distribution of collateral blood flow during coronary arterial occlusion may be distinctly different in the right and left ventricles.[16] Thus, special conditions may be required for right ventricle infarction, a view that is supported by the results of animal experiments.[17–19] In the pig, occlusion of the right coronary artery consistently produced infarction of the posterior left ventricle and interventricular septum but not of the right ventricle.[17] However, when occlusion of the right coronary artery was preceded by right ventricular hypertrophy and pulmonary hypertension, infarction of the right ventricle followed the occlusion and collateral blood flow from the left anterior descending coronary artery to the bed of the right coronary artery was slow to develop.[17,19] Because neither our patients nor those reported on in other studies[7–9] of combined right and left ventricular infarction had a significant incidence of right ventricular hypertrophy or pulmonary hypertension, these observations on collateral blood flow may

be germane to an understanding of the pathogenesis of right ventricular infarction.

The common pattern of atherosclerosis in our series was severe stenosis or occlusion of the left anterior descending and right coronary arteries, which confirms the observations of Isner and Roberts.[9] Because the left anterior descending coronary artery is the primary source of collateral blood flow for the right coronary artery, collateral blood flow to the right ventricle may have been impeded in these cases.[18,19] This hypothesis is in accord with the findings in experimental animals and in patients. Dwyer et al.[20] reported that in patients with occlusion of the right coronary artery, collateral circulation was more extensive in those patients whose electrocardiograms were not diagnostic of an infarction of the inferior wall of the left ventricle. Correlations between right ventricular infarction and acute thrombotic occlusion of the right coronary artery have been noted previously in a small number of cases,[21] but the general relation of acute coronary arterial lesions and right ventricular infarction has not previously been reported. Our study indicates that fatal combined right and left ventricular infarction is associated with an unusually large incidence of acute coronary arterial lesions (Table III), an occurrence that should not be ascribed to cardiogenic shock or congestive heart failure because their incidence was similar in the two groups (Table I). These acute lesions, both occlusive and nonocclusive, were distributed throughout the coronary arterial tree, even though they occurred most commonly in the right coronary artery (Table IV). Bloor and White[22] showed that in a compromised coronary circulation with complex collateral flow, an acute occlusion or stenoses will result in an abrupt reduction in collateral flow throughout the system. Thus, it seems reasonable to suggest that acute coronary arterial lesions might lead to the development of right ventricular infarction by causing an abrupt decrease in collateral blood flow in severely atherosclerotic coronary arteries.

Clinical Features of Left Main Equivalent Coronary Disease

JOSEPH D. BABB, MD, FACC
RICHARD G. SCHMIDT
THOMAS M. BERARD, MD
JOHN M. FIELD, MD, FACC

Hershey, Pennsylvania

The clinical presentation and hemodynamic, ventriculographic and coronary arterial findings of 70 patients with left main equivalent coronary artery disease (70 percent or greater reduction in luminal diameter of the left anterior descending and left circumflex vessels prior to any major branches) were compared with those of 75 patients with 60 percent or greater reduction in luminal diameter of the left main coronary artery. The group with left main equivalent disease did not differ significantly from the group with left main stenosis in any clinical descriptors including New York Heart Association functional class, age, sex distribution, type of presenting symptom or history of congestive heart failure or myocardial infarction. Similarly, the two groups did not differ in ejection fraction, cardiac index, left ventricular end-diastolic pressure, left ventricular end-diastolic volume index, extent of left ventricular contraction abnormality or prevalence of associated significant right coronary arterial obstruction.

Of the 70 patients with left main equivalent disease, 31 were deemed to be in operable condition but did not undergo coronary bypass surgery for 1 or more months (mean 4.2 months, range 1 to 12). With the exception of four patients who underwent early operation because of unremitting symptoms, the groups undergoing early and delayed operation did not differ in symptomatic state. In the interim between cardiac catheterization and delayed operation, no patient died and one patient (3 percent) had an acute myocardial infarction. These low morbidity and mortality rates differ strikingly from those of patients with left main stenosis reported in the randomized Veterans Administration study, although the patients in the two studies manifested comparable severity of symptoms, extent of left ventricular contraction abnormality and associated right coronary disease.

The results suggest that left main equivalent disease, as defined by obstruction of the left anterior descending and circumflex coronary arteries, does not carry the same short-term prognosis as left main coronary artery disease, but probably behaves more like ordinary two or, if the right coronary artery is also obstructed, three vessel coronary artery disease. In this sense, the term left main equivalent disease is a misnomer causing an unnecessary sense of urgency and alarm.

From the Division of Cardiology, The Milton S. Hershey Medical Center, The Pennsylvania State University, College of Medicine, Hershey, Pennsylvania. Manuscript received May 1, 1979; revised manuscript received August 15, 1979, accepted September 10, 1979.

Address for reprints: Joseph D. Babb, MD, Division of Cardiology, Milton S. Hershey Medical Center, Hershey, Pennsylvania 17033.

Significant lesions of the left main coronary artery are known to be associated with considerable impairment of left ventricular function and a large incidence of occlusive disease in other coronary vessels.[1–4] These facts partly explain the poor survival and high early mortality rates of patients with such lesions.[1,2,4] In contrast, there have been few studies of left main equivalent disease, which has been called "an entity not yet well defined."[5] However, the term "equivalent" implies that the characteristics of this lesion, including its natural history, are comparable with those of left main coronary artery disease; hence, in many patients

with left main equivalent disease immediate coronary arterial bypass surgery is performed in the hope that revascularization will improve survival as it does for patients with left main coronary artery disease.[4,6–9] In this investigation we attempted to provide a better definition of left main equivalent disease and to assess and compare its hemodynamics, clinical presentation, and early natural history with those of left main coronary artery disease.

Methods

Patient Selection

Data on all cardiac catheterization studies involving coronary arteriography performed in adults from July 1975 to June 1978 were reviewed to identify patients with significant left main coronary artery disease or left main equivalent disease. This review yielded 75 patients with significant left main coronary artery disease and 70 patients with left main equivalent disease. These represented 5 and 4.5 percent, respectively, of all patients undergoing coronary arteriography.

Significant left main coronary artery disease was defined as 60 percent or greater reduction of luminal diameter of the left main coronary artery, with or without any combination of stenotic lesions in other coronary arteries. *Left main equivalent disease* was defined as 70 percent or greater reduction in luminal diameter of the left anterior descending and circumflex arteries prior to any ventricular branches or immediately after the first septal artery or the first marginal artery, or both, only if the latter vessels had 70 percent or greater stenoses in their immediate proximal segment. Patients were not classified as having left main equivalent disease if they had 30 percent or greater reduction in luminal diameter of the left main coronary artery. Although no restrictions were placed on right coronary artery disease or adequacy of left ventricular function, patients with hemodynamically significant valvular heart disease were excluded from the study.

Cardiac catheterization films involving multiple views of each coronary artery were then reviewed to confirm the presence of one or more of the reported lesions in the left coronary arterial system and to record the severity of any associated right coronary artery disease. Inclusion in the study requires independent confirmation of each case by all investigators.

Clinical Data

Clinical presentation: The hospital records of every patient included in the study were reviewed with respect to age, sex, New York Heart Association functional classification,[10] nature and duration of presenting symptoms and history of previous myocardial infarction or congestive heart failure. Presenting symptoms were classified as chronic stable, progressive or unstable angina pectoris. Progressive angina pectoris was defined as angina that gradually increased in frequency or severity, or both, over several months; unstable angina pectoris was defined as angina that abruptly and markedly increased in severity and occurred without identifiable provocation within the preceeding 4 weeks. Previous myocardial infarction was substantiated by the presence of Q waves in electrocardiographic tracings and by documented serum enzyme changes.

Hemodynamics: Left ventricular function was assessed by measuring four continuous hemodynamic variables and by evaluating regional left ventricular contraction pattern. It is protocol at our institution to terminate administration of propranolol and all long-acting nitrates approximately 10 hours before study. Anginal pain occurring during this time is treated with sublingual nitroglycerin. All left ventricular function studies were performed prior to coronary arteriography.

The four hemodynamic variables used were left ventricular end-diastolic pressure, ejection fraction, cardiac index and end-diastolic volume index. Ejection fraction was derived from biplane anteroposterior and lateral cineventriculograms; cardiac index was obtained from duplicate indocyanine green determinations and end-diastolic volume index was determined by dividing end-diastolic volume, derived from biplane cineventriculograms, by total body surface area. Regional left ventricular contraction pattern was assessed by visual inspection of each patient's biplane cineventriculogram. Wall motion was characterized as abnormal if any hypokinetic, akinetic or dyskinetic wall motion was seen. Abnormal contraction patterns were anatomically localized to four left ventricular segments: apical, anterolateral, anterior and inferior.

Natural history: To determine the early natural history of left main equivalent disease we studied the incidence of myocardial infarction or death, or both, in patients with this disease whose condition was considered operable but who did not undergo coronary bypass surgery for 1 or more months after cardiac catheterization. At our institution, many patients with left main equivalent lesions, unlike patients with anatomic left main coronary artery disease, do not undergo immediate revascularization but are discharged and maintained on standard medical therapy until surgery can conveniently be scheduled.

Statistical analysis: Data are expressed as mean values ± standard error of the mean. Comparisons were made using Student's t test for continuous variables or chi square analysis for noncontinuous variables.

Results

Clinical presentation (Table I): Table I summarizes the clinical characteristics of the patients with left

main coronary and left main equivalent disease. There were no significant differences between the two groups with regard to New York Heart Association functional class, sex, mean duration of symptoms, type of presenting symptoms and history of congestive heart failure or myocardial infarction.

Left ventricular function (Tables II and III): Tables II and III summarize the hemodynamic and left ventricular contraction variables in the two patient groups. There were no significant differences between groups with regard to ejection fraction, cardiac index, left ventricular end-diastolic pressure and volume index and frequency of normal or abnormal left ventricular contraction or severity and number of abnormally contracting left ventricular segments.

Associated right coronary artery disease (Table IV): No significant differences were noted between the two patient groups in prevalence or severity of associated right coronary disease.

Natural history: Of the 70 patients with left main equivalent disease, 15 (21 percent) were judged to be in inoperable condition and 24 (34 percent) underwent coronary bypass surgery within 1 month of catheterization. In 4 of the latter patients, operation was performed early because of unremitting, severe ischemic symptoms in spite of maximal medical therapy; in the other 20 it was performed early because operative time was available rather than because of medical urgency. Of these 24 patients 13 were in functional class IV (including all 4 who underwent urgent operations), 7 in class III and 4 in class II.

Thirty-one of the 70 patients (44 percent) were considered to be in operable condition but experienced a delay of more than 1 month between catheterization and bypass surgery. During this period, they continued to receive standard medical therapy with nitrates and beta adrenergic blocking drugs. Surgery was delayed in these 31 patients for the following reasons: Eighteen patients accepted surgical recommendation immediately but could not be accomodated in the operative schedule for several weeks; of these, eight were in class IV, nine in class III, and one in class I. Nine patients (four in class IV, four in class III and one in class II) wished to consider their options further before making a commitment to surgery. Four patients (three in class III and one in class II) refused recommended surgery. The distribution of patients by functional class in these groups did not differ statistically.

Of these 31 patients who refused operation or underwent late operation 1 (3 percent) had a myocardial infarction and none died. The mean duration of medical management subsequent to cardiac catheterization was 4.2 ± 0.8 months (median 3.6 months; range 1 to 12 months).

2	23 (33%)	26 (35%)
3	14 (20%)	10 (13%)
4	5 (7%)	6 (8%)

n = number of patients.

Discussion

Left main equivalent disease, as defined in this report, was associated with the same clinical presentation and overall left ventricular function as significant left main coronary artery disease (60 percent or greater reduction in luminal diameter). The incidence and extent of associated right coronary artery disease were also similar; thus, most patients with left main equivalent disease had three vessel obstructive coronary artery disease, as is true of most patients with left main coronary disease. Of our patients with left main disease, 9 had associated one vessel disease, 17 associated two vessel disease, 46 associated three vessel disease and 3 no associated coronary disease.

Prognosis of left main equivalent versus left main coronary disease: Left ventricular function, the number of diseased vessels and certain noninvasive features (class IV angina, history of congestive failure,

for example) are useful predictors of survival in patients with coronary artery disease, including disease of the left main coronary artery.[11–13] However, our study strongly suggests that patients with left main equivalent disease do not demonstrate the same natural history and, specifically, the high early mortality associated with significant left coronary stenosis. The incidence of myocardial infarction (3 percent) and death (0 percent) in our 31 patients with operable left main equivalent disease who received standard medical therapy for more than 1 month (mean 4.2 months) after cardiac catheterization was appreciably lower than that of the 53 patients with significant but operable left main coronary stenosis randomly assigned to a prospective medical treatment group in the Veterans Administration Cooperative Study.[4] At 4.2 months after randomization, 8 (15 percent) of those 53 patients had died. The data from this large prospective randomized study are in close agreement with findings in other retrospective medical series.[1,2]

The increased survival rate of our 31 patients with left main equivalent disease cannot be attributed to better overall left ventricular function, lack of severe obstructive disease or more favorable clinical presentation. In fact, a comparison of available features (Table V) reveals that class IV angina, abnormal left ventricular contraction, abnormal left ventricular function and associated right coronary disease were more prevalent in our patients with left main equivalent disease then in the patients with left main stenosis in the Veterans Administration study. However, the improved survival in our group may be explained by considering the location of the lesions. Significant stenoses of the left main coronary artery are particularly ominous because they tend to occur in association with coexisting disease of other major coronary vessels.[1–4] Because critical stenoses in series have additive effects on blood flow,[14] mild progression of disease can have a catastrophic effect on coronary blood supply. Additionally, although independent stenoses of the left anterior descending and circumflex coronary arteries may have an apparent equivalency to a single main left lesion, these more distal stenoses may change independently to alter the clinical situation. Thus, an abrupt change of an 80 percent lesion of the left main coronary artery to a subtotal stenosis may have catastrophic effects on blood flow in the entire left coronary system, whereas a similar change in a lesion of the left anterior descending coronary artery with a stable, coexisting 80 percent lesion in the circumflex artery would affect only a portion of the left coronary system distribution. The remaining coronary beds might be able to compensate for the decreased coronary flow with new collateral vessels.

Eighty percent of our patients with left main equivalent disease had severe triple vessel disease. Thus, our study also indicates that patients with triple vessel disease amenable to surgical intervention may not experience the high early mortality reported by Bruschke et al.[14] but demonstrate a natural history more closely resembling that of patients with operable triple vessel disease as reported by Murphy et al.[15]

TABLE IV

Associated Right Coronary Artery Disease in Patients With Left Main Equivalent Disease and Left Main Coronary Artery Disease

Percent Reduction in Luminal Diameter of Right Coronary Artery	Left Main Equivalent Disease (n)	Left Main Coronary Artery Disease (n)
Normal	1 (1%)	5 (7%)
Present but <50%	3 (4%)	2 (3%)
50 to 70%	10 (14%)	7 (9%)
Significant disease		
70 to 90%	13 (19%)	17 (23%)
90% to subtotal	7 (10%)	13 (17%)
100%, proximal	31 (44%)	29 (40%)
100%, mid or distal	5 (7%)	2 (3%)

n = number of patients.

Implications: In our study, left main equivalent disease was associated with the same clinical presentation and overall left ventricular function as left main coronary stenosis. However, our findings strongly suggest that patients with left main equivalent lesions amenable to surgical intervention do not share the natural history and high early mortality of patients with significant disease of the left main coronary artery but

TABLE V

Clinical and Ventricular Function Data in Patients With Operable Left Main Equivalent Disease (present study) and Medically Treated Patients With Significant Left Main Coronary Artery Disease (VA study[4])

	Left Main Equivalent Disease (present study) (n)	Left Main Coronary Artery Disease (VA study) (n)
NYHA class		
I	1 (3%)	2 (4%)
II	2 (6%)	19 (36%)

IV	8 (25%)	2 (4%)
Age	57 years	54 years
Duration of angina in months		
0–12	14 (45%)	19 (36%)
13–24	2 (6%)	6 (11%)
25–60	8 (26%)	12 (23%)
60	7 (23%)	16 (30%)
History of prior MI	21 (65%)	30 (67%)
History of CHF	5 (16%)	4 (8%)
Abnormal LV size	10 (23%)	13 (25%)
Abnormal LV contraction	28 (90%)	24 (45%)
Ejection fraction <0.50	13 (42%)	15 (28%)
Abnormal LV function*	28 (90%)	33 (62%)
RCA disease with abnormal LV function	28 (90%)	30 (56%)

* Left ventricular function was considered abnormal if any one of the following variables was present: ejection fraction less than 0.50, left ventricular end-diastolic pressure greater than 14 mm Hg, left ventricular enlargement, abnormal contraction pattern.

CHF = congestive heart failure; LV = left ventricular; MI = myocardial infarction; n = number of patients; NYHA = New York Heart Association functional class; RCA = right coronary artery; VA = Veterans Administration.

demonstrate a natural history more closely resembling that of patients with operable two or three vessel disease. This finding has obvious implications. Because patients with left main equivalent disease are apparently not at high risk for early myocardial infarction or death, long-term prospective studies on the benefits of medical versus surgical therapy in patients with this lesion could be undertaken with reasonable safety. Furthermore, such patients need not be hospitalized after catheterization in preparation for urgent surgery but can be discharged on standard medical therapy to return when surgery is conveniently scheduled. This practice would considerably reduce hospital costs and afford the patient greater opportunity for emotional adjustment when the option of delayed surgery is considered reasonable or advisable.

Mechanism of the Repetitive Ventricular Response in Man

H. LEON GREENE, MD, FACC
PHILIP R. REID, MD, FACC
ALLEN H. SCHAEFFER, MD

Baltimore, Maryland

The electrophysiologic characteristics of the repetitive ventricular response that followed an electrically induced single premature ventricular complex were evaluated to determine its mechanism during atrial pacing or sinus rhythm in 30 patients. Seven patients had preexisting bundle branch block. His bundle or right bundle branch deflections did not precede the repetitive complex in 29 of the 30 patients, which implies that the proximal His-Purkinje system was not involved in the reentry circuit. In 24 of 30 patients the QRS axis of the repetitive complex was divergent 45° or more from the stimulated complex. In 22 of 30 patients the repetitive complex had a right bundle branch block configuration. In 14 of 18 patients with two or more repetitive complexes, the QRS pattern changed from beat to beat, which implies that either the reentry pathway or conduction was changing. Thus, the repetitive ventricular response, which can be associated with clinically important ventricular arrhythmias, probably represents intraventricular rather than proximal His-Purkinje system reentry.

Right ventricular premature stimulation during right ventricular pacing can produce reentry that incorporates the proximal His-Purkinje system and bundle branches, even in normal subjects.[1–4] Characteristics of this reentry within the proximal His-Purkinje system have been summarized by other authors[1,5] to include the following: (1) His bundle deflections (H_2) precede the reentry beat (V_3). (2) Time from onset of premature ventricular stimulus to retrograde His bundle activation (V_2-H_2 interval) is prolonged. (3) The interval from retrograde His bundle deflection to the reentry QRS complex (H_2-V_3 interval) is normal or prolonged. (4) The QRS configuration of the reentry complex (V_3) is often similar to that of the paced complex, that is, a left bundle branch block, left axis deviation configuration. (5) The premature stimulus (S_2), which induces a premature ventricular complex (V_2), which in turn may initiate a third spontaneous reentry complex (V_3), often must be closely coupled to the basic driving ventricular stimulus (S_1), presumably causing retrograde block in the right bundle branch. (6) Most often the reentry is not sustained and it consists of only a single complex (V_3 phenomenon). (7) Bundle branch or proximal His-Purkinje system reentry occurs commonly in any normal or abnormal subject with normal intraventricular conduction, but it is rare in patients who have preexisting bundle branch block.

We have defined the "repetitive ventricular response" as the production of two or more ventricular premature complexes in response to a single ventricular pacing stimulus during sinus rhythm or atrial pacing. The repetitive ventricular response has identified a predisposition to spontaneous ventricular arrhythmias—a form of ventricular electric instability—in certain groups of patients.[6] Other investigators have suggested that initiation of sustained ventricular arrhythmias by other

programmed stimulation techniques correlates with spontaneous rhythm disturbances in these same patients and that normal subjects without spontaneous ventricular arrhythmias will not have sustained ventricular arrhythmias induced by this type of testing.[7–9] Elimination of the repetitive ventricular response (as we have defined it) by intravenous aprindine, an experimental antiarrhythmic agent, was associated with the long-term success of aprindine given orally.[10] However, questions have arisen[11,12] regarding the mechanism of production of the repetitive ventricular response as we have defined it. We[6] have suggested that the predictive value of the repetitive ventricular response during atrial pacing or sinus rhythm must depend on a mechanism of reentry different from proximal His-Purkinje or bundle branch reentry. In this study we evaluated the mechanism of production of the repetitive ventricular response elicited during atrial pacing or sinus rhythm in 30 patients.

Methods

Study patients: The records of all patients who underwent any type of intracardiac electrophysiologic stimulation or recording studies, or both, between September 1975 and March 1979 at The Johns Hopkins Hospital were reviewed (Table I). Two hundred twenty-one patients were tested for the repetitive ventricular response, as previously described,[6] and 92 patients were found to have it. In 30 of the 92 patients an additional catheter had been positioned to allow recording of His bundle or right bundle branch potentials, and these 30 patients form the basis of this report. Findings in these 30 patients are compared with findings in the total group of 92 patients with the repetitive ventricular response to demonstrate that the two groups are comparable in all other respects.

Electrophysiologic technique: All patients were in a postabsorptive and nonsedated state at the time of the electrophysiologic study. Informed consent was obtained, and all drugs known to affect cardiac conduction or refractoriness were discontinued 48 hours before the study, except in the patients with ventricular tachycardia who had a second electrophysiologic study while taking oral antiarrhythmic agents chronically. Electrode catheters were inserted percutaneously or by a cutdown in the femoral or antecubital veins and were positioned in the right atrium and right ventricle. An additional catheter was positioned to record His bundle or right bundle branch potentials. The ventricular catheter was first positioned at the apex of the right ventricle so that there were no mechanically induced premature complexes.

Pacing stimuli were 0.9 ms in duration at twice diastolic threshold and never greater than 4.0 mA. Either the right atrium was paced at a 700 ms interval or the patient was allowed to remain in a condition of spontaneous sinus rhythm. A single ventricular stimulus was introduced every eighth beat, initially at the QRS complex, and was progressively moved toward the preceding T wave by 10 to 20 ms intervals until it reached the end of the T wave, when it was further moved toward the peak of the T wave in 10 ms intervals. Electric diastole was scanned with the ventricular stimulus in this manner until ventricular refractoriness was reached or until repetitive ventricular responses were produced. These responses were defined as two or more ventricular premature complexes in response to a single ventricular stimulus that were reproducible and obtained while the catheter was in a stable position free of mechanically induced ventricular complexes. At similar coupling intervals the repetitive responses were observed at least twice, and almost always three times, in order to be considered reproducible. A second position in the right ventricle (usually the right ventricular outflow tract) was stimulated in this manner if repetitive ventricular responses were not identified in the first position.

Multiple surface electrocardiograms (leads I, II, III, aVR, aVL, aVF and V_1 with or without other precordial leads) and intracardiac electrograms (right atrial and His bundle or right bundle branch electrograms) were recorded simultaneously with an Electronics for Medicine VR-12 physiologic recorder and stored on a Hewlett-Packard model 3968 FM magnetic tape recorder for subsequent review. Cardiac stimulation was accomplished with a programmable digital stimulator and isolated constant-current source (Bloom Associates).

Characteristics of repetitive ventricular responses: *Conduction system deflections:* In all 30 patients in whom either a His bundle or right bundle branch deflection was being recorded during the stimulation techniques, the presence or absence of a His bundle or right bundle deflection between the stimulated and repetitive complexes was ascertained. Although absence of conduction system deflections can result from catheter movement or fractionation and subsequent loss of amplitude of potentials, the patients were carefully evaluated for these phenomena. All patients included in this report had reliable recordings of His or right bundle potentials obtained while catheter positions were stable.

QRS configuration: The frontal or horizontal plane QRS axis, or both, was evaluated to determine whether the QRS

TABLE I

Study Patient Characteristics

Patients (n)	Total	Patients With Symptomatic Ventricular Tachycardia: No Antiarrhythmic Drugs	Patients With Symptomatic Ventricular Tachycardia: Oral Antiarrhythmic Drugs	Survivors of Recent Acute MI	Normal Subjects	Patients With Ischemic Heart Disease: No Recent MI or Arrhythmias
Total tested	221	77	25	61	22	36
With repetitive ventricular response	92	66	3	22	0	1
With repetitive ventricular response with HBE or RBE recordings	30	24	0	6	0	0

HBE = His bundle electrogram; MI = myocardial infarction; RBE = right bundle electrogram.

configuration of the repetitive complexes was similar to the QRS configuration of the complex induced with electric stimulation from the right ventricular catheter. Results were expressed as the change in degrees of frontal or horizontal plane QRS axis (whichever was greater) between stimulated and repetitive complexes.

Q-stimulus/Q-T ratio: The prematurity of the ventricular pacemaker stimulus required to elicit the repetitive ventricular response was expressed by the ratio of the interval from the onset of the Q wave of the preceding QRS complex to the stimulus of the electrically induced complex (Q-stimulus) to the Q-T interval for that patient, measured in the multiple simultaneously recorded electrocardiographic leads. Thus, if a closely coupled stimulus elicited the repetitive ventricular response, the Q-stimulus/Q-T ratio would be low. If a stimulus late in diastole elicited the repetitive response, the Q-stimulus/Q-T ratio would be high.

Number of sites tested: Patients were classified according to whether the repetitive ventricular response was elicited at the first or second right ventricular pacing site. The first site was the right ventricular apex, and in those patients whose repetitive response was not elicited in the first site, the second site was either the right ventricular outflow tract or right ventricular inflow tract.

Number of repetitive complexes: The maximal number of repetitive complexes after the electrically induced complex was counted in each patient with attention to (1) whether His bundle or right bundle deflections were associated with subsequent QRS complexes, and (2) whether the QRS frontal or horizontal plane axis was changing in subsequent complexes.

Complications: Among the 221 patients tested for the repetitive ventricular response who form the basis of this report, sustained ventricular tachycardia developed in 4 patients (1.8 percent) during testing, requiring either overdrive pacing (1 patient) or external electric cardioversion (3 patients). None of the four patients had any sequelae from these arrhythmias or from cardioversion. No other complications occurred during this study.

More than one repetitive beat	16 (53%)	44 (48%)

H-V = time from onset of His deflection to onset of QRS; Q-stimulus/Q-T = interval from onset of QRS to stimulus that elicits repetitive ventricular response divided by Q-T interval; VF = ventricular fibrillation; VT = ventricular tachycardia; ± = standard deviation.

Results

Patient Characteristics

Patients with the repetitive ventricular response who had evaluation of His or right bundle branch deflections (n = 30): These results are presented in Tables I and II. Eleven of these patients had survived an episode of ventricular fibrillation not associated with an acute myocardial infarction, and an additional four patients had experienced syncope due to sustained ventricular tachycardia documented by Holter or coronary care unit monitoring.

All patients with the repetitive ventricular response (n = 92): There were 22 survivors of an acute myocardial infarction who had the repetitive ventricular response. The mean time from myocardial infarction to study (± standard deviation) was 31 ± 30 days (range 8 to 120). Of the 69 patients with recurrent symptomatic ventricular tachycardia and the repetitive response, 21 had survived an episode of cardiac arrest requiring cardiopulmonary resuscitation; the episode was accompanied by documented ventricular fibrillation or hypotensive ventricular tachycardia not associated with an acute myocardial infarction. An additional seven patients had experienced syncope due to ventricular tachycardia documented on ambulatory or continuous coronary care unit monitoring. Among the 40 patients with coronary artery disease, old myocardial infarction and recurrent symptomatic ventricular tachycardia, the time from the most recent myocardial infarction to study ranged from 14 days to 24 years.

In the total group of 92 patients with the repetitive ventricular response, therefore, 69 patients had coronary artery disease with a mean of 1.4 ± 1.0 (range 0 to 5) myocardial infarcts. Only six patients with coronary artery disease had never had a myocardial infarction diagnosed clinically. No normal subjects had the repetitive ventricular response.

Characteristics of the Repetitive Ventricular Response (Tables II through V)

Conduction system deflections: Of the 30 patients who had recordings of His bundle or right bundle branch deflections, 29 had findings suggesting that proximal His-Purkinje system or bundle branch reentry was not the mechanism for the repetitive ventricular response (Fig. 1 through 5, Table III).

In 25 patients the His bundle deflections were present when the patient had sinus rhythm, but could not be identified before the repetitive complex occurred. In six of these patients the His potential could be identified *within* the QRS deflection of the repetitive complex.

In four additional patients in whom a right bundle branch deflection was recorded, the right bundle branch potential did not precede the repetitive complex. In three of these patients the right bundle potential could be identified *within* the QRS deflection of the repetitive complex (Fig. 2, bottom) and in one patient it could not be identified before or within the repetitive complex. In one of these four patients a His bundle deflection was also identified *within* the QRS complex of the repetitive beats (Fig. 3). Although recording of a right bundle branch potential within the repetitive complexes in these three patients does not ensure that bundle branch reentry is not occurring, the surface QRS pattern in the first repetitive complex had a right bundle branch block pattern, and in three of these four patients successive repetitive complexes had a different QRS configuration with the right bundle deflection still located within the QRS complex. Although these findings are still less than absolutely confirmatory, their pattern does not fit the findings most commonly reported for bundle branch reentry.

In only one patient did a His bundle deflection occur between the induced and repetitive QRS complexes with retrograde V_2-H_2 prolongation, finding compatible with reentry within the proximal His-Purkinje system.[2] However, in this patient the repetitive complex did not have a left bundle branch block configuration. In 9 of 10 patients in whom a retrograde His or right bundle (RB) deflection was positively identified, retrograde V_2-H_2 or V_2-RB_2 delay was not necessary for the production of the repetitive response. In the remaining 20 patients, His and right bundle deflections were recorded during anterograde conduction but were absent before the repetitive complexes. Therefore, retrograde V_2-H_2 or V_2-RB_2 delay did not seem to be necessary for the repetitive ventricular response.

The His-Purkinje system was, in fact, diseased in some patients. The mean H-V interval for the 30 patients in whom His or right bundle potentials were evaluated during ventricular stimulation was 54 ± 14 ms. However, in only four patients was the H-V interval greater than 60 ms. In the entire group of 92 patients with the repetitive response, the H-V interval was 52 ± 13 ms. Fractionated His bundle potentials were carefully sought. If catheter movement or fractionation of potentials was suspected, the catheter position was adjusted and stimulation was repeated with careful attention being paid to low-voltage potentials between stimulated and repetitive beats recorded from the His bundle catheter.

QRS configuration: Of the 30 patients who had His or right bundle potentials monitored during ventricular stimulation, 4 had preexisting right bundle branch block and 3 had preexisting left bundle branch block. Similarly, in 13 of the total of 92 patients with repetitive ventricular response either right (8 patients) or left (5 patients) bundle branch block was manifested in the surface electrocardiogram during normal sinus rhythm.

The angles between the QRS axis of the electrically induced complex and the repetitive complex are summarized in Table IV. In 22 of the 30 patients who had His bundle or right bundle branch potentials monitored during ventricular stimulation, the repetitive complex had a right bundle branch block configuration. The repetitive complexes also had this configuration in 51 of the 92 patients with the repetitive ventricular response.

Q-stimulus/Q-T ratio: In the 30 patients evaluated with His or right bundle recordings the mean Q-stimulus/Q-T ratio was 1.19 ± 0.30. In 64 of the 92 patients with the repetitive ventricular response, the Q-stimulus/Q-T ratio was 1.0 or greater; in 73 patients the ratio was 0.9 or greater. Local conduction delay (latency) was not required to produce the repetitive responses.

Number of sites tested: In 13 (14 percent) of the total group of 92 patients testing of a second right ventricular site was necessary to produce the repetitive

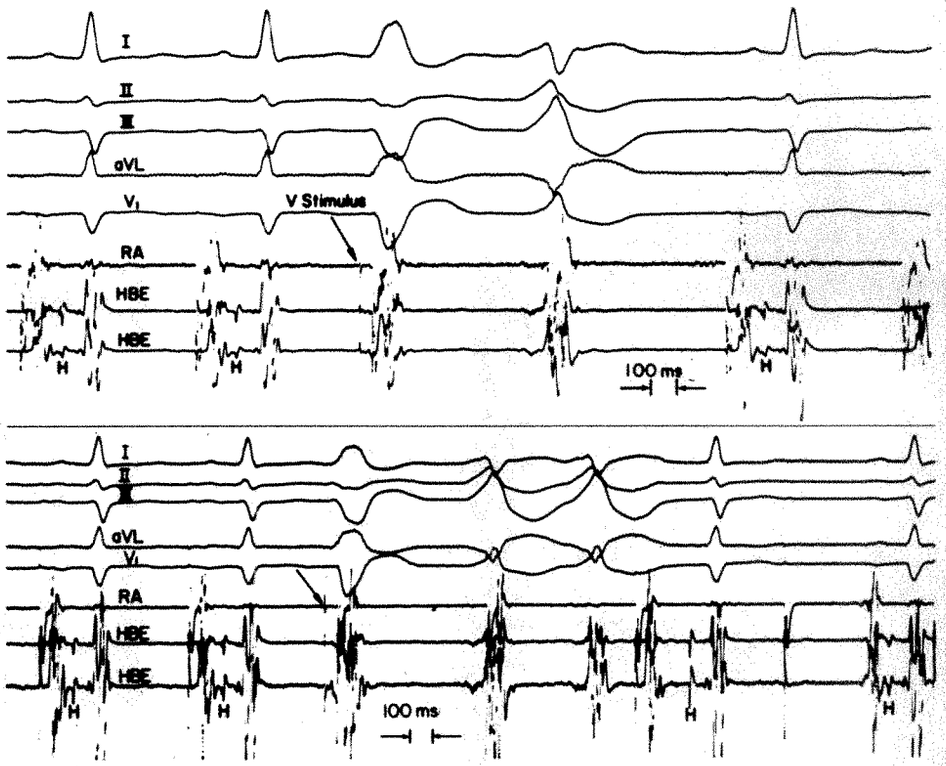

FIGURE 1. Repetitive ventricular response. Leads I, II, III, aVL, V_1, right atrial (RA) and two His bundle electrograms (HBE) are simultaneously recorded. **Top,** a single premature ventricular stimulus (V stimulus) evokes a single repetitive response having a morphologic pattern different from that of an electrically stimulated complex. His bundle deflections (H) precede the QRS complexes during atrial drive and anterograde conduction, but His bundle deflection cannot be identified between stimulated and repetitive complexes. **Bottom,** the ventricular stimulus **(arrow)** is nearer the T wave and two repetitive responses of the same configuration result. The repetitive responses have a different configuration from that of the electrically stimulated complexes and no His bundle deflections (H) can be identified before the repetitive complexes.

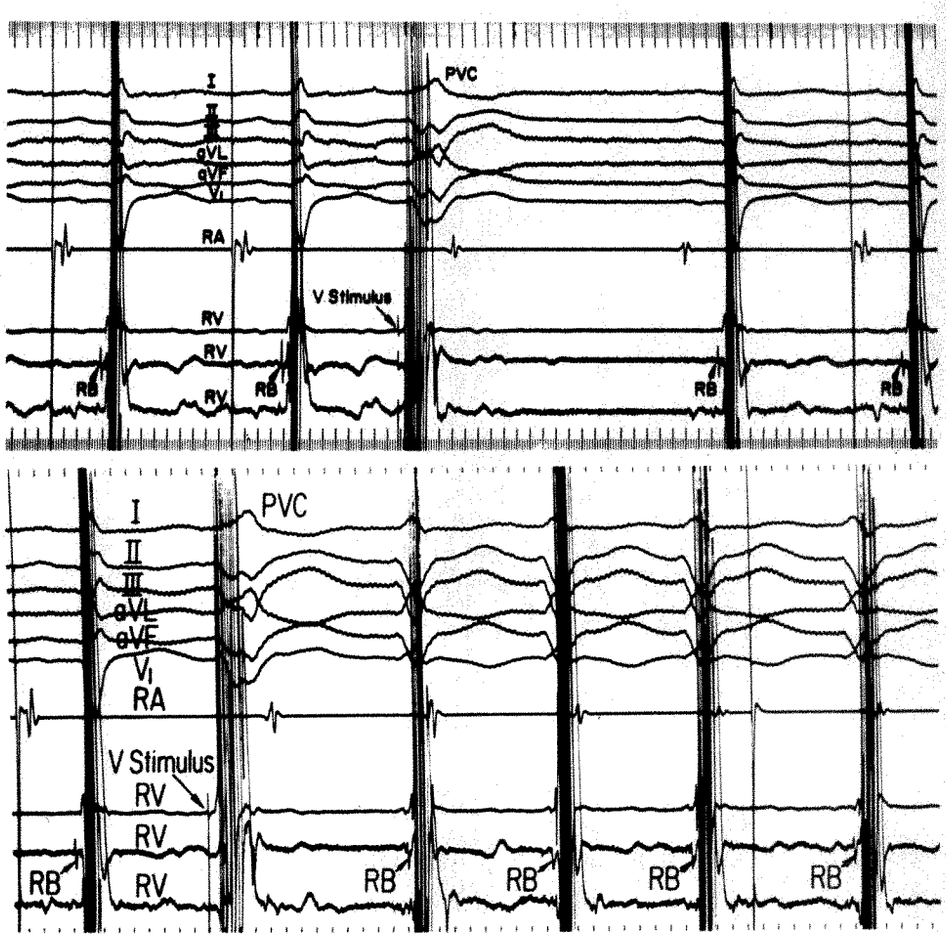

FIGURE 2. Repetitive ventricular response. Leads I, II, III, aVL, aVF, and V_1 and right atrial (RA) and three ventricular electrograms (RV) are recorded simultaneously. Right bundle branch potentials (RB) are recorded in the latter electrograms. **Top,** a single ventricular stimulus during atrial drive (V stimulus) produces only a single premature ventricular complex (PVC), but **(bottom)** a stimulus closer to the T wave results in a short burst of ventricular tachycardia. During this tachycardia the QRS configuration is different from that of the stimulated complex, and right bundle potentials occur within the QRS complex, thus implying that the reentry pathway does not include the right bundle branch. Large time lines occur at 50 ms intervals.

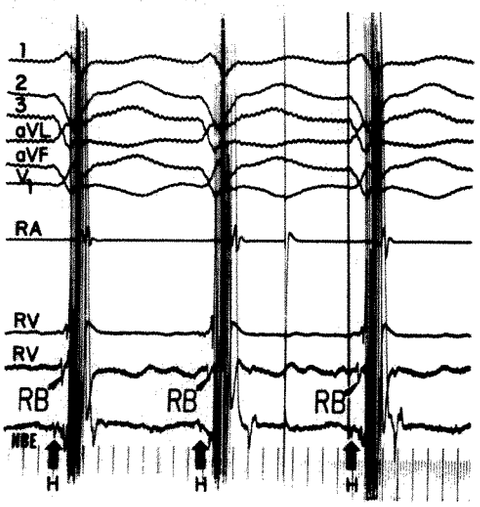

FIGURE 3. Same patient as in Figure 2 during sustained ventricular rhythm. The right ventricular catheter had been withdrawn slightly and His bundle potentials (H) are being recorded *within* the QRS complex in the lowest electrogram. The **solid vertical line** marking the onset of the last QRS complex on the right illustrates that both His bundle and right bundle branch deflections followed the onset of the QRS complex, thus implying that the conduction system was being activated incidentally and that the His-Purkinje system was not incorporated in the reentry circuit. Further evaluation of this patient for accessory atrioventricular conduction pathways failed to produce any evidence for accessory pathways active in either an anterograde or retrograde direction. Unidentified abbreviations as in Figures 1 and 2.

FIGURE 4. Repetitive ventricular response. Leads I and aVL recorded simultaneously in a patient who had no His bundle recordings during the ventricular stimulation studies. A single ventricular stimulus **(arrow)** during sinus rhythm evokes four repetitive responses after the electrically stimulated complex. The QRS pattern of the repetitive complexes is different from that of the stimulated complex and it changes slightly from complex to complex.

ventricular response. In those 13 patients the QRS axis between the stimulated and repetitive complex was 125 ± 63°. In addition, the repetitive complex had a right bundle branch block configuration in seven of these patients.

Number of repetitive complexes: Sixteen of the 30 patients who had His bundle or right bundle branch potentials monitored during ventricular stimulation had more than one repetitive complex and in 14 of these 16 patients the QRS configuration was changing. In the total group of 92 patients, 48 had only one repetitive complex after the stimulated complex (Table V). If this finding was reproducible, further stimulation was not performed. However, 27 of the 44 patients who had more than one repetitive complex had QRS complexes that were changing on subsequent repetitive complexes, which implies that the reentry pathway or conduction was changing. More than one repetitive complex was as common in patients who were as in those who were not evaluated with the additional His or right bundle recordings.

Evidence for absence of proximal His-Purkinje or bundle branch reentry: All 30 patients with the repetitive ventricular response who had His bundle or right bundle branch recordings had one or more findings suggesting that His-Purkinje or bundle branch reentry was not the mechanism for the repetitive complexes: (1) absence of a His bundle or right bundle deflection preceding the repetitive complexes; (2) complexes diverging 45° or more from stimulated complexes if stimulation was performed at the apex of the right ventricle, or not exhibiting a left bundle branch block and left axis deviation pattern if stimulation was performed elsewhere; (3) right bundle branch block configuration of the repetitive complexes; (4) a continuously changing QRS pattern in the presence of more than one repetitive complex; or (5) lack of critical V_2-H_2 prolongation necessary for proximal His-Purkinje reentry. In only six patients could proximal His-Purkinje or bundle branch reentry possibly have been responsible for the repetitive complexes. On the other hand, none of the entire group of 30 patients met all of the criteria for proximal His-Purkinje or bundle branch reentry. The repetitive ventricular response occurred in the presence or absence of preexisting conduction defects; it occurred both in patients who had and in those who had not experienced spontaneous ventricular fibrillation; and it occurred both in the presence and absence of coronary artery disease and myocardial infarction.

Discussion

Most patients with chronic and recurrent sustained ventricular tachycardia can have ventricular rhythm disturbances initiated in the electrophysiology laboratory with timed ventricular premature stimulation.[9,13,14] Wellens[13] and Josephson[5,15] and their co-workers were able to initiate and terminate ventricular tachycardia reliably in these patients. However, other investigators[16] were unable to reproduce consistently the patients' arrhythmias. All of these studies used multiple ventricular stimulation in an attempt to produce sustained ventricular tachycardia. Mason and Winkle[17] and Horowitz et al.[18] demonstrated that a drug that suppresses the ability to induce ventricular tachycardia in the electrophysiology laboratory will likewise suppress spontaneous ventricular tachycardia when that drug is given for long periods. All of these studies represent a form of electrophysiologic "stress testing" to expose ventricular electric instability, that is, the propensity to spontaneous ventricular arrhythmias. Our technique for eliciting the repetitive ventricular response to expose ventricular electric instability perhaps represents a

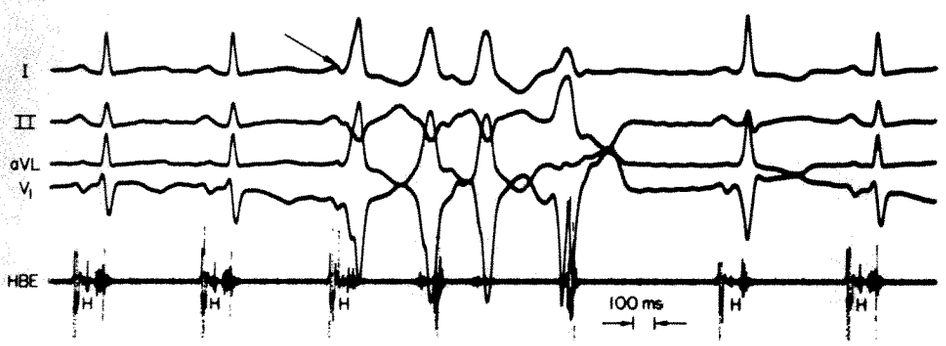

FIGURE 5. Repetitive ventricular response in another patient during sinus rhythm. Surface leads I, II, aVL and V_1 are recorded simultaneously with a His bundle electrogram (HBE). His bundle potentials (H) are associated with QRS complexes conducted in anterograde manner. The **arrow** indicates a single ventricular extrastimulus late in diastole. Three repetitive complexes follow the electrically induced complex. The first two have a QRS configuration similar to that of the electrically induced complex, whereas the last repetitive QRS complex has a slightly different configuration. His bundle potentials are not associated with any of the repetitive complexes.

milder form of stress than multiple sequential ventricular stimuli since sustained ventricular tachycardia is not required as an end point. With atrial pacing or sinus rhythm, simply the production of repetitive ventricular complexes after a single ventricular stimulus has been used as an indicator of ventricular electric instability and has been shown to have predictive value in (1) survivors of a recent myocardial infarction[6] and (2) patients with chronic recurrent ventricular tachycardia treated intensively with aprindine, an investigational antiarrhythmic drug.[10]

Bundle branch reentry: Several groups of investigators[1–4] have defined characteristics of reentry within the proximal His-Purkinje system that can be elicited even in normal subjects. With constant-rate ventricular pacing followed by ventricular premature stimulation, reentry within the His-Purkinje system can occur when there is a critical delay between the ventricular premature stimulus and the retrograde His-Purkinje system activation ("re-HPS", the "V_3 phenomenon" or "bundle branch reentry"). This technique of ventricular drive with ventricular premature stimulation has been used to evaluate the characteristics of reentry within the proximal His-Purkinje system and the effects of drugs on reentry in this tissue. This type of reentry is relatively common and can be seen in most patients with normal intraventricular conduction. The reentry circuit is most often dependent on retrograde conduction block in the right bundle with conduction through ventricular muscle to the left bundle, retrograde progression of activation to the area of the His bundle, and anterograde propagation of the impulse down the right bundle, which has regained conductivity. This type of reentry often produces a QRS configuration of a left bundle branch block, similar to that of the paced complexes from the apex of the right ventricle, although other patterns of reentry have been described. Rarely does this type of reentry produce sustained ventricular tachycardia.

Intraventricular reentry: Josephson and colleagues[5,15] have defined another type of reentry, which they have termed "intraventricular reentry," differing from "bundle branch reentry." In their studies in patients with chronic ventricular arrhythmias, ventricular tachycardia that did not require reentry within the proximal His-Purkinje system could reliably be induced. Retrograde conduction block in the right bundle branch was not necessary for initiation of ventricular tachycardia, and a retrograde V_2-H_2 delay likewise was not required. The QRS configuration of the ventricular tachycardia induced by electric stimulation was similar in most cases to that of the spontaneous ventricular tachycardia for which the patient had been referred for study. These investigators were able to initiate and terminate the tachycardia reproducibly with programmed stimulation, and this finding implies a reentry circuit. Other evidence suggested that the reentry site was a small portion of the ventricles. Sustained ventricular tachycardia could most reliably be produced with ventricular premature stimuli introduced during ventricular drive, whereas only rarely was sustained ventricular tachycardia induced by single or double ventricular stimuli during atrial drive or sinus rhythm. We have also noted a greater incidence of sustained ventricular tachycardia in patients with chronic ventricular tachycardia during ventricular drive and single or multiple ventricular premature stimulation than during atrial drive and single premature ventricular stimulation. In addition, nonsustained intraventricular reentry can often be elicited with single ventricular premature stimulation during ventricular drive when it could not be obtained during atrial drive or sinus rhythm.

Repetitive ventricular response in patients with recurrent sustained ventricular tachycardia: Reentry within the proximal His-Purkinje system thus seems common in normal subjects with ventricular pacing and ventricular drive, but sustained ventricular tachycardia rarely ensues. In patients who have a history of ventricular tachycardia or who are at risk of subsequent development of ventricular tachycardia, sustained ventricular tachycardia may occur during electrophysiologic testing with ventricular premature stimulation, but this phenomenon frequently represents intraventricular reentry, which does not utilize the proximal His-Purkinje system.[19] It seems unusual that

the repetitive response, as we have defined it, has not been observed in other laboratories with ventricular drive and premature ventricular stimulation. However, it does not occur in normal subjects and it rarely occurs even in the patient with coronary disease, except in the survivor of a recent myocardial infarction who is at high risk of late symptomatic ventricular tachycardia or sudden death. It occurs most predictably in the patient with recurrent sustained ventricular tachycardia.

Ventricular pacing with ventricular premature stimulation may establish ideal circumstances for retrograde block within the right bundle branch to allow proximal His-Purkinje system reentry, whereas ventricular premature stimulation during atrial drive or sinus rhythm would tend to make His-Purkinje system reentry less likely. With anterograde propagation of the impulse through the His-Purkinje system (during atrial drive or sinus rhythm), premature ventricular stimulation may fail to find the right bundle branch or other divisions of the His-Purkinje system refractory at a time conducive to reentry within this system.

Our study demonstrates that the repetitive ventricular response obtained during atrial drive or sinus rhythm is not dependent on retrograde V_2-H_2 delay. In only 1 of 30 patients was a retrograde His bundle deflection present before the ventricular reentry complex. Even in this single patient, other characteristics of the reentry (the QRS configuration) suggested that reentry was not occurring within the bundle branches, but that the bundle branches were coincidently being activated simultaneously, while the reentry was occurring elsewhere. Although surface QRS patterns can be misleading when one is trying to ascertain the site of the origin of a QRS complex, in most patients the surface QRS configuration of the repetitive complex suggested reentry on the left side of the heart with a right bundle branch block pattern and QRS axis dissimilar to the QRS axis of the stimulated complex.

Akhtar and colleagues[2] reported differing routes of impulse propagation during reentry within the proximal His-Purkinje system in human subjects. However, only 15 percent of their patients had reentry with a right bundle branch block pattern. In addition, 13 of our patients had preexisting bundle branch block during sinus rhythm, which would make reentry within the proximal His-Purkinje system less likely. Similarly, the QRS configuration was commonly changing in our patients with more than one repetitive complex, implying that reentry was not occurring repetitively within the same His-Purkinje system circuit. Likewise, a low Q-stimulus/Q-T ratio (close coupling interval) was seldom required for initiation of repetitive ventricular responses, a condition that is usually required for reentry within the proximal His-Purkinje system where retrograde block in the right bundle is necessary.[1]

Local reentry in diseased ventricular muscle: We postulate that the repetitive ventricular response as we have defined it represents reentry within diseased tissue, perhaps terminal Purkinje fibers, ventricular muscle or, in many cases, a ventricular aneurysm or scar because many of our patients had a history of recent or remote myocardial infarction. Although the overall ejection fraction was normal in many patients, all but one patient had an abnormal left ventricular contraction pattern on angiography with localized disease of ventricular muscle. Supporting the concept that diseased tissue is necessary for the repetitive ventricular response is our finding that other patients without fixed myocardial disease and who have a history of ventricular arrhythmias during certain transient phenomena do not have the repetitive ventricular response under basal conditions. This was true in four of our patients with coronary arterial spasm-induced ischemia and four patients with fixed coronary arterial obstructive disease without myocardial infarction but with ventricular tachycardia during exercise-induced ischemia. It appears that the repetitive ventricular response is absent unless there is fixed disease of ventricular muscle or unless ischemia is produced with provocative maneuvers (induction of coronary arterial spasm with ergonovine or induction of ischemia with exercise or atrial pacing). In addition, only 1 of our 36 patients with coronary artery disease without myocardial infarction had the repetitive ventricular response in the absence of pacing-induced ischemia, although proximal His-Purkinje system reentry can be produced with ventricular pacing and ventricular premature stimulation in these patients as it can be produced in normal subjects.

Role of electrophysiologic testing: prognostic value: These findings highlight the concept that in many patients there are at least two factors that generate ventricular arrhythmias: (1) an initiating event, such as a premature ventricular depolarization, and (2) a substrate on which the initiating event can work to produce a sustained, clinically important arrhythmia. In the electrophysiology laboratory the initiating event is artificial—the introduction of ventricular premature stimuli. These testing procedures cannot easily reproduce the spontaneous events that initiate out-of-hospital clinical rhythm disturbances. Moreover, although these testing procedures can expose a chronic substrate for ventricular arrhythmias, even the substrate may change with acute events such as the induction of ischemia. Therefore, the value of these electrophysiologic tests may be limited by the inability to simulate either (1) those transient factors that may provide the initiating event, or (2) the acutely altered substrate necessary for the spontaneous generation of a clinical rhythm disturbance.

Nonetheless, it would seem that the mechanism of reentry is important to any prognostic value of these electrophysiologic tests. Repetitive complexes characteristic of proximal His-Purkinje reentry that are induced during ventricular drive and ventricular premature stimulation occur commonly in normal persons and are generally of no prognostic singificance. These repetitive complexes are usually not sustained to produce ventricular tachycardia. On the contrary, reentry that does not utilize the proximal His-Purkinje system and that results in sustained ventricular tachycardia

during ventricular drive and ventricular premature stimulation is seen only in patients with a history of ventricular tachycardia or in patients with electrically unstable ventricles. "Repetitive ventricular reponses" during atrial drive or normal sinus rhythm occur by a mechanism of reentry that does not appear to involve the proximal His-Purkinje system. Whether it is necessary to produce sustained intraventricular reentry for electrophysiologic testing procedures to have prognostic value for spontaneous arrhythmias is unknown. Unsustained intraventricular reentry itself may be sufficient to identify the electrophysiologic substrate that will sustain a clinically significant rhythm disturbance and have prognostic importance for the prediction of both (1) symptomatic ventricular tachycardia or sudden death, and (2) the response to antiarrhythmic medications. However, because other authors[11,12,20] have used the term "repetitive ventricular response" to describe other types of ventricular reentry phenomena, it may be advantageous simply to use the more descriptive terms (either "intraventricular reentry" or proximal "His-Purkinje reentry") in future studies.

Superior QRS Axis of Ventricular Premature Complexes: An Additional Criterion to Enhance the Sensitivity of Exercise Stress Testing

T. JOSEPH MARDELLI, MD
JOEL MORGANROTH, MD, FACC
LEONARD S. DREIFUS, MD, FACC

Philadelphia, Pennsylvania

The presence or frequency of ventricular premature complexes during exercise is not highly predictive for identifying patients with coronary artery disease. To determine whether the morphologic features or axis of exercise-induced ventricular premature complexes may increase this predictability, a study was made of 63 symptomatic patients with coronary artery disease (electrocardiographic evidence of infarction or occlusive lesions seen on coronary angiography, or both) and 10 control patients with normal coronary arteriograms. In 48 of the 63 patients with coronary artery disease the exercise-induced ventricular premature complexes had a superior frontal plane QRS axis between −30° and −120°; in 12 the axis was between −30° and +150°, and in 2 the axis was indeterminate, between +150° and −120°. In all 10 control subjects without coronary artery disease the QRS axis of the exercise-induced ventricular premature complexes was in the normal range, between −30° and +150°. If the standard criterion of 1 mm S-T segment depression were used to predict coronary artery disease during exercise stress testing, 25 of the 63 patients with coronary artery disease would have had a normal or borderline exercise test. However, in 21 of these 25 patients the exercise-induced ventricular premature complexes had a superior axis, a criterion that would enhance the predictive sensitivity of the exercise test from 60 to 94 percent. A left bundle branch block pattern of ventricular premature complexes was not helpful in detecting patients with coronary artery disease, although a right bundle branch block pattern was infrequent in the control subjects. The occurrence of ventricular premature complexes with a superior axis during exercise testing can enhance the exercise test's sensitivity for detecting the presence of coronary artery disease, particularly when this criterion is used in patients with a nondiagnostic S-T segment response to exercise.

Exercise stress testing is performed to detect or to confirm the presence of coronary artery disease or myocardial ischemia. The criterion of 1 mm S-T segment depression in symptomatic patients[1] is somewhat limited, with a sensitivity reported between 60 and 70 percent and a specificity of 90 percent. The additional variables of angina,[2] high grade ventricular arrhythmias,[3] hypotension[4] and an increasing R wave amplitude[5] during exercise are adjunctive findings that may increase the diagnostic usefulness of exercise stress testing. More recently, a multivariate approach has been employed to improve sensitivity and specificity.[6,7] Unfortunately, the presence or frequency of ventricular ectopic complexes during exercise stress testing has been found to have a low correlation with the presence of underlying coronary disease.[8,9] Several investigators[10–12]

have attempted to correlate the site of origin of ventricular premature complexes with the presence and location of cardiac disease. However, except for the morphologic designation of right or left bundle branch block, precise quantitation of form as well as the axis of ventricular premature complexes has not been applied to proved cases of coronary artery disease. We sought in this study to evaluate an additional variable in the analysis of stress testing, namely, the morphology or axis, or both, of ventricular premature complexes occurring during exercise as a means of enhancing the sensitivity of this important noninvasive test.

Methods

Exercise tests: The exercise stress tests of approximately 750 patients referred to our noninvasive laboratory were reviewed for the presence of ventricular premature complexes. The Bruce protocol was used in all exercise tests, and a multichannel recording system (Marquette Exercise Stress Test System) producing a 15 lead electrocardiogram (12 standard leads plus X, Y and Z orthogonal leads) was used during each stage of the protocol. Lead sets I-II-III, aVR-aVL-aVF, V_1-V_2-V_3, V_4-V_5-V_6 and X-Y-Z were simultaneously recorded. The patient's electrocardiogram was monitored throughout the test, and additional selective strips were recorded in each patient whenever ventricular arrhythmia or S-T segment

CAD = coronary artery disease; ECG = electrocardiogram; IRBB = incomplete right bundle branch block; IVCD = intraventricular conduction defect; LAH = left anterior hemiblock; LBBB = left bundle branch block; LVH = left ventricular hypertrophy; Positive = significant S-T depression; RBBB = right bundle branch block; VPCs = ventricular premature complexes.

depression was noted. All stress tests were continued until maximal heart rate was attained or symptoms such as angina, dyspnea or exhaustion occurred. S-T segment depression of 2 mm or greater was another criterion used to terminate a study. No complications or adverse reactions occurred.

Patients: Seventy-three persons with ventricular premature complexes occurring during exercise in which the axis and morphologic features (right or left bundle branch block pattern) could be determined were evaluated. Sixty-three patients had evidence of coronary artery disease manifested by either a pattern of transmural myocardial infarction in the electrocardiogram (50 patients) or angiographic findings of occlusive coronary artery disease (50 percent or greater luminal narrowing) in one or more of the coronary arteries (24 patients). Eleven of the 63 patients had both criteria. This group of 63 patients was compared with 10 subjects who had ventricular premature complexes during exercise testing but who had normal coronary and left ventricular cineangiograms. Patients who had conditions known to affect the S-T segment analysis during exercise, such as hypertrophic cardiomyopathy, mitral valve prolapse, valvular heart disease, conduction abnormalities or preexcitation syndrome, or who were taking digitalis were excluded.

The axis of the ventricular premature complexes occurring during exercise was determined by the presence of at least one such complex in the limb leads, and the configuration was judged from either the V_1 or Z leads to be either right or left bundle branch block. A superior axis was defined as an axis of the ventricular premature complex between −30° and −120°. An axis between +150° and −120° was considered indeterminate, whereas the axis of all other observed complexes was between −30° and +150°. Patients in whom the ventricular premature complexes showed multiple axes were classified according to the superior axis if present.

Results

Ventricular premature complexes in 63 patients with documented coronary artery disease (Table I): Forty-five of 63 patients showed uniform ventricular

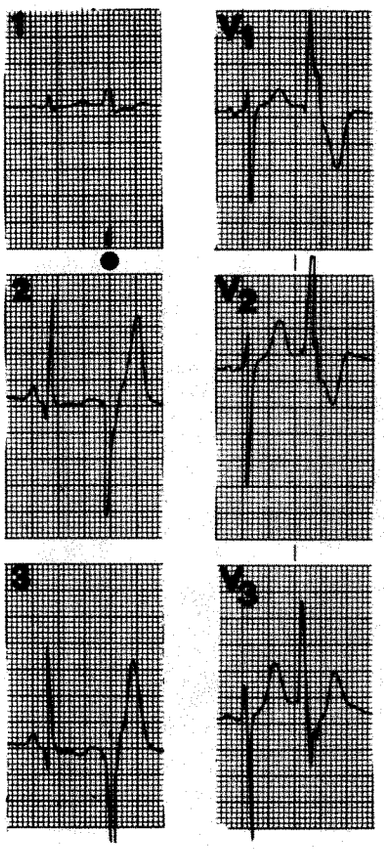

FIGURE 2. Example of an exercise-induced ventricular premature complex in a patient with coronary artery disease and inferior wall myocardial infarction; there is an abnormal superior axis (approximately −75°) and a right bundle branch block configuration.

premature complexes, whereas 18 had complexes with multiple axes. The distribution of the axes and the morphologic features are shown in Figure 1. At least one ventricular premature complex with a superior axis between −30° and −120° was observed in 48 patients (76 percent) (Fig. 2). Thirteen patients (21 percent) had a ventricular premature complex with an axis between −30° and +150°. Two patients had ventricular premature complexes with an indeterminate axis. Thirty-seven patients had a right bundle branch block pattern alone (59 percent), 16 patients a left bundle branch block pattern alone (27 percent), and 10 (14 percent) patients had ventricular premature complexes with instances of both right and left bundle branch block patterns (Fig. 3).

The sensitivity for coronary artery disease of a superiorly directed axis of the ventricular premature complex was 76 percent (24 percent false negative). The distribution of the axes of the ventricular premature complexes among the 63 patients with coronary artery disease classified by infarction pattern in the resting electrocardiogram is depicted in Figure 4. Thirty-eight patients had an inferior scar, and ventricular premature complexes with a superior axis were present in 33 (87 percent); 12 patients had a pattern of anterior infarction, 5 of whom (42 percent) had a superior axis. Ten (77 percent) of the 13 patients with angiographic findings of multiple scars or multiple coronary occlusive lesions, or both, had exercise-induced ventricular premature complexes with a superior axis.

Of the 24 patients with angiographic evidence of coronary artery disease, 8 had single vessel, 4 had two vessel and 12 had three vessel coronary artery disease. The distribution of ventricular premature complexes in these 24 patients is shown in Figure 5. The axis in 17 (71 percent) was superior, and in 16 (67 percent) there was a right bundle branch block pattern.

When the criterion of S-T segment depression alone was used to determine the presence of coronary artery disease during exercise testing in the 63 patients with such disease, only 38 had an abnormal S-T segment response of 1 mm or greater depression. Twenty-five patients had a normal or borderline test with 1 mm or less S-T segment depression. However, 21 (84 percent) of these 25 patients had a ventricular premature complex with a superior axis (Table I). Thus, the sensitivity of the exercise test using the S-T segment depression criterion alone was enhanced from 60 to 94 percent when the axis of exercise-induced ventricular premature complexes was considered.

Patients with normal coronary arteriogram and left ventriculogram: There were 10 instances of ventricular premature complexes in which the axis and morphology could be evaluated in the 10 control subjects (Table II). Figure 6 shows the distribution of these ventricular premature complexes according to their axis and morphologic features. In all 10 subjects (100 percent) the axis was between −15° and +110° (Fig. 7). There was no instance of a superior axis. Nine of 10 ventricular premature complexes showed a left

Electrocardiogram at rest (**left**) from a patient with coronary artery disease and an inferior wall myocardial infarction; the axis of the ventricular premature complex is in the normal range (approximately +40°) with a left bundle branch block configuration. During exercise (**right**) there are ventricular premature complexes with an abnormal superior axis (approximately −75°) with the orthogonal (X, Y and Z) leads demonstrating first a ventricular premature complex with a left and then a right bundle branch block pattern.

bundle branch block and one a right bundle branch block pattern.

Discussion

Our results demonstrate that the axis of ventricular premature complexes occurring during exercise may yield important information that may enhance the sensitivity of exercise testing in symptomatic patients with underlying coronary artery disease. When S-T segment depression alone is utilized in symptomatic populations, the sensitivity of the exercise test in large part depends upon the number of diseased coronary vessels.[1,13] The use of adjunctive findings during testing such as angina,[2] hypotension[4] or serious repetitive ventricular ectopic complexes[3] may be of additional help. The actual occurrence or frequency of ventricular

arrhythmia has not been particularly helpful in distinguishing those subjects with coronary artery disease.[8,9,14]

Significance of site of origin of ventricular premature complexes: In all 10 patients with angiographically proved normal coronary arteries the exercise-induced ventricular premature complexes had an axis of −15° to +110°. Therefore, the specificity of this finding is 100 percent (0 percent false positive). In the 63 patients with coronary artery disease the presence of an axis of −30° to −120° of such exercise-induced complexes showed a sensitivity of 76 percent (24 percent false negative), which is slightly superior to that of the S-T segment criterion alone (60 percent). Furthermore, the configuration of ventricular premature complexes (right or left bundle branch block) has not been of additional help. Previous studies[11,15,16] have analyzed the site of origin and the axis of ventricular ectopic complexes in the electrocardiogram obtained at rest. Bodenheimer et al.[11] showed a poor correlation between

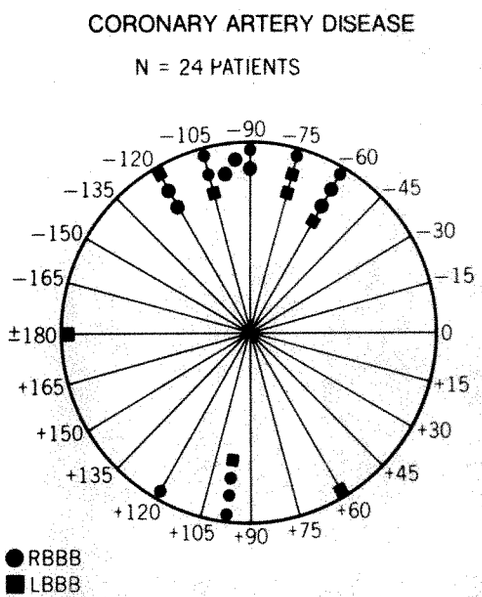

FIGURE 5. Distribution of the axes of exercise-induced ventricular premature complexes in 24 patients with coronary artery disease documented by coronary arteriography. Symbols and abbreviations as in Figure 1.

the site of origin of ventricular premature complexes and the prevalence or severity of coronary artery disease. Talbot and co-workers[15] found that ventricular premature complexes with a left bundle branch block pattern and with a vertical or right axis were most frequent in normal subjects, but in the presence of cardiac disease a right bundle branch block pattern occurred more frequently.

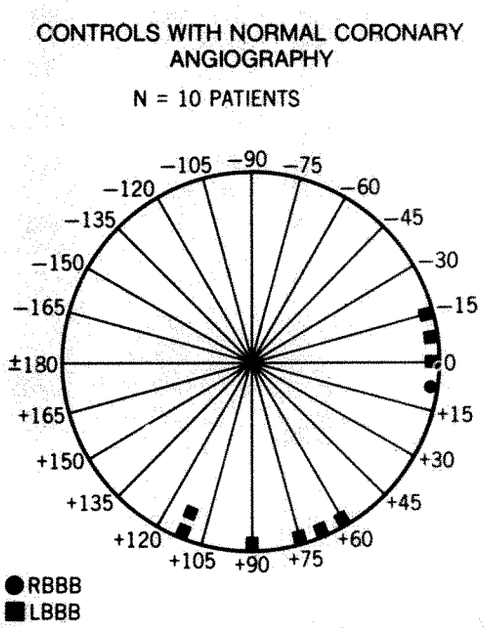

FIGURE 6. Distribution of exercise-induced ventricular premature complexes in 10 patients serving as control subjects, who had normal coronary angiograms. Symbols and abbreviations as in Figure 1.

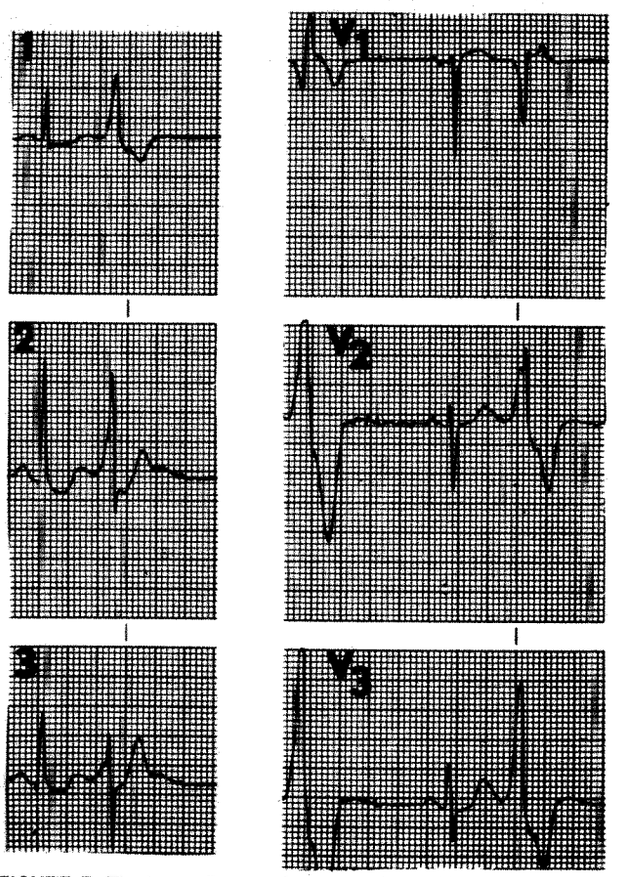

FIGURE 7. Electrocardiogram from a patient with normal coronary arteriograms. Exercise-induced ventricular premature complexes are seen with a normal frontal plane axis (approximately +10°) with a right bundle branch block configuration.

Watanabe et al.[12] suggested that ventricular premature systoles are more likely to originate from an area of intraventricular conduction delay, and that the ectopic impulse seems to invade and at least partially utilize the other fascicles of the Purkinje system for ventricular excitation. Lewis et al.[10] noted an association between right, left and biventricular ventricular premature complexes with the respectively diseased ventricule or ventricles and they reported that patients without organic heart disease had ventricular premature complexes of right ventricular origin. However, Kaplinsky and associates[17] concluded that ischemic damage to the left ventricle produced ventricular arrhythmia that appeared to originate from both ventricles, depending on the exit site from the subendocardium of the left ventricle. Recently, Josephson et al.[16] reported that ventricular premature complexes originating from the site of a ventricular aneurysm demonstrated either a right or a left bundle branch block pattern, or both. The ventricular premature complexes in all their patients had a superior axis.[16] Hence, the limitations are now established of the surface electrocardiogram in deriving the ventricular site of origin from the morphology of the ventricular premature complex. However, the axis of the ventricular premature complex has the potential of differentiating normal persons from those with coronary artery disease. Ventricular premature complexes with a right bundle branch block configuration were rarely seen (10 percent) in normal control subjects in our study, whereas in patients with documented coronary artery disease, right bundle branch block was present alone in 59 percent, left bundle branch block alone in 27 percent and both right and left bundle branch block in the remaining 14 percent of patients.

Ventricular premature complexes with a superior axis during exercise were found more commonly in patients with electrocardiographic evidence of isolated inferior myocardial infarction than in those with isolated anterior infarction (87 versus 42 percent, $p < 0.01$). In patients with an inferior myocardial scar, the site of origin of the ventricular premature complex is inferoposterior and therefore its axis is likely to be superior; but in patients with an anterior scar the axis of the ventricular premature complex will depend on the site of its origin, which may be in the basal or apical segment of the heart. Whether these data will be helpful for analysis of ventricular premature complexes recorded in the electrocardiogram at rest remains to be determined.

Implications: Our data suggest that although ventricular premature complexes with a vertical axis during exercise may occur both in normal persons and in patients with coronary artery disease, such complexes with an abnormal superior axis appear to be a specific marker for coronary artery disease. The use of this criterion adjunctively with S-T segment depression may increase the sensitivity of exercise stress tests in those patients with nondiagnostic studies. However, not every patient shows ventricular premature complexes during exercise and therefore this additional criterion is limited to those patients in whom this finding is observed. Technicians who are alert to ventricular ectopic complexes occurring during exercise should be instructed to record additional electrocardiographic strips to facilitate analysis of the axis of any documented ventricular premature complexes.

Effects of Exercise Training on Left Ventricular Function in Normal Subjects: A Longitudinal Study by Radionuclide Angiography

STEPHEN K. RERYCH, MD
PETER M. SCHOLZ, MD
DAVID C. SABISTON, Jr., MD, FACC
ROBERT H. JONES, MD, FACC*

Durham, North Carolina

Radionuclide angiocardiography provides accurate hemodynamic information during maximal exercise in erect subjects. Cardiac function was studied with this noninvasive technique in 12 male and 6 female college athletes before (BT) and after (AT) 6 months of swimming training. Measurements at rest and during maximal exercise of heart rate, left ventricular ejection fraction, end-diastolic volume, cardiac output and total body blood volume were determined from first pass and equilibrium precordial counting techniques. The results were as follows:

	Heart Rate (beats/min)	Ejection Fraction (%)	End-Diastolic Volume (ml)	Cardiac Output (liters/min)	Total Body Blood Volume (liter)
Rest					
BT	74 ± 11	73 ± 6	133 ± 35	6.9 ± 1.1	8.7 ± 0.8
AT	61 ± 7	67 ± 7	167 ± 40	6.7 ± 1.0	11.4 ± 2.2
Exercise					
BT	185 ± 10	87 ± 4	166 ± 34	25.5 ± 5.7	8.0 ± 0.9
AT	181 ± 14	86 ± 5	204 ± 39	32.0 ± 8.7	10.8 ± 2.3

Total body blood volume increased after training ($p < 0.03$). Although cardiac output was similar at rest before and after training, a decrease in heart rate ($p < 10^{-4}$) and ejection fraction ($p < 10^{-3}$) was associated with an increase in end-diastolic volume ($p < 10^{-5}$). Cardiac output at maximal exercise increased ($p < 0.02$) after training because of an increased end-diastolic volume ($p < 10^{-4}$) with a constant heart rate and ejection fraction. Individual variation was observed in the performance level achieved, and the maximal cardiac output at exercise achieved after training (56.6 liters/min) was attained by an Olympic athlete. Exercise training appears to enhance cardiac performance primarily by inducing cardiac dilatation.

Intensive exercise training can lead to extraordinary levels of cardiac performance in well trained athletes.[1] Although several studies[2–7] have examined the physiologic adaptation of the heart in response to exercise training, their results have not produced a unified concept of the effect of exercise conditioning on the heart.[8–11] Changes in heart rate, left ventricular muscle mass, chamber size, stroke volume, cardiac output and maximal oxygen consumption have been documented but the effect of other variables of left ventricular performance during maximal exercise in the erect position have not been fully assessed. Radionuclide

angiocardiography is a relatively new technique that provides accurate noninvasive assessment of cardiac function at rest and maximal exercise.[12,13] With use of a single radionuclide injection, this technique measures left ventricular ejection fraction, left ventricular end-diastolic volume, pulmonary transit time, pulmonary blood volume and total body blood volume. The left ventricular ejection fraction is calculated from the stroke volume and end-diastolic volume. Calculation of the left ventricular stroke work and the end-diastolic volume provides data necessary to evaluate the left ventricle from the perspective of the Frank-Starling law of the heart.[14] The radionuclide technique is the only approach feasible for measuring the left ventricular stroke work and end-diastolic volume in erect subjects during maximal exercise at very high heart rates under physiologic conditions.

This report is the first description of the use of radionuclide angiocardiography to evaluate the influence of physical training on ventricular function in the normal subject. In addition to enhancing the understanding of the cardiovascular response to exercise conditioning in normal subjects, these data may prove useful for comparison with subsequent similar studies in patients with cardiac disease.

Methods

Data Acquisition

Study group: Radionuclide angiocardiograms were obtained to assess cardiac function in 18 normal athletes before and after a 6 month period of intensive training for competitive swimming. The group was selected at random from the North Carolina State University swimming team and consisted of 12 male and 6 female varsity athletes who consented to the study. The mean age of the group was 19 years. The mean body surface area was 1.94 ± 0.14 m^2 before training and 1.96 ± 0.14 m^2 after training. The primary exercise during this period was swimming, but other types of exercise including jogging with weight lifting were also encouraged. Social and dietary adjustments associated with training were not controlled but appeared to change in a manner compatible with standard athletic training regimens. After informed consent was obtained from each subject, a history, physical examination, chest radiograph and electrocardiogram were obtained to exclude preexisting cardiopulmonary disease.

Radionuclide angiocardiography: Radionuclide angiocardiograms at rest and during exercise were obtained immediately before both the initiation and the conclusion of an intensive 6 month period of training for competitive swimming. Our radionuclide angiocardiographic technique for evaluating cardiac function at rest and during maximal exercise, previously described in detail, was used for the study. The evaluation before and after training consisted of a resting and exercise study performed 3 to 7 days apart. The study at rest was performed before the exercise study in nine randomly selected subjects; in the remaining nine subjects the exercise study was performed first. For each study, measurement of height and weight were obtained. A sphygomomanometer was applied for blood pressure measurements, and a CM_5 precordial electrocardiographic lead was monitored by telemetry. A 2.5 cm, 20 gauge Teflon® catheter was inserted into an external jugular vein and connected to a saline-filled three-way stopcock, 50.8 cm intravenous tubing and a 20 ml syringe. The Baird-Atomic System Seventy-Seven multicrystal gamma camera® with a 1.5 inch (3.8 cm) parallel multihole collimator was used to record precordial counts during initial tracer transit. The detector of the instrument was positioned directly anterior to the precordium. Data were acquired with subjects sitting erect on the bicycle ergometer during a period of hemodynamic stability confirmed with pulse and blood pressure measurements. Data recording at 50 ms intervals was continued for a total period of 60 seconds. Immediately after initiation of data recording, 25 mCi of technetium-99m labeled human serum albumin was introduced through the stopcock into the intravenous tubing and injected as a discrete tracer bolus using a brisk injection of 20 ml of saline solution.

The technique used to obtain the radionuclide angiocardiogram during exercise was identical to that used for the study at rest except that the injection was made during maximal exercise stress. Handlebars on the gamma camera permitted the subjects to stabilize their chest to prevent motion artifact while maintaining a vigorous level of exertion. Subjects exercised in the erect position on a Tunturi® bicycle ergometer for a period of 10 minutes with increasing resistance in increments at 2 minute intervals from 2 newtons to a maximum of 8 newtons. The pedal frequency of the bicycle ergometer was determined by the ability of the subject to tolerate the resistance level. The total equivalent distance traversed in kilometers was recorded at the end of each exercise. The high motivation and competitive response of the varsity athletes made unnecessary the imposition of a maximal work level. All subjects reached exhaustion during exercise studies in an attempt to attain the highest performance level possible.

Cardiac output and blood volume: In addition to data from the radionuclide angiocardiogram a 60 second precordial equilibrium count was obtained 10 minutes after tracer administration for calculation of cardiac output using the indicator-dilution principles and technique previously applied to radionuclide data.[15,16] At the same time, a 5 ml sample of blood was obtained from an antecubital vein. Determination of the level of radioactivity in the blood sample and assessment of the total radioactive dose was obtained by correcting the amount initially in the syringe for that remaining in the syringe and tubing after administration. This calculation provided a measurement of total body blood volume by the dilution principle.[17]

Data Processing

Definition of cardiac regions and borders: Systolic and diastolic blood pressures recorded simultaneously with the studies at rest and during exercise were used to estimate the mean systemic arterial pressure by adding one third of the pulse pressure to the diastolic pressure.[18,19] The radionuclide data were processed using the Volume II and Volume III software for the Baird-Atomic System Seventy-Seven computerized multicrystal gamma camera. This instrument achieves counting rates greater than 400,000 counts/s at counting intevals as brief as 10 ms. The first step in data processing is to relate observed counts to discrete cardiac regions. Borders of cardiac chambers were defined by a recently developed method based on a description of the time function of counts observed in many small regions over the precordium.[20] The time description reflects the individual cardiac chamber delay with bolus transit of tracer, thus permitting accurate delineation of cardiac chamber boundaries. In any projection, anatomic overlap of adjacent cardiac chambers occurs. Complex curves with several individual components are recorded over these adjacent cardiac regions. These curves are separated, using a computer technique, into individual

components with each curve characterized by total counts and by mean chamber transit time. Techniques for determining the pulmonary mean transit time and pulmonary blood volume have been described elsewhere.[13] The mean transit time is directly related to volume and is inversely proportional to flow. Therefore, the pulmonary blood volume (in milliliters) is calculated by multiplying the cardiac output (in milliliters per second) by the pulmonary mean transit time (in seconds).

Ejection fraction and heart volumes: Accurate delineation of anatomic regions is particularly important for the calculation of left ventricular ejection fraction. The latter is calculated from the left ventricular volume curve, which is obtained from the background corrected left ventricular counts throughout a single cardiac cycle. Determination of ejection fraction in 33 patients demonstrated a correlation coefficient of 0.89 between the value obtained with this radionuclide technique and that obtained with biplane contrast ventriculography in the right and left anterior oblique projections.[13]

A computer program outlined the end-diastolic and end-systolic perimeters at the 21 percent isocount contour of the end-diastolic image. Previous imaging of elliptical phantoms filled with 5 mCi of technetium-99m pertechnetate in water demonstrated a 21 percent count level to correspond most closely to the phantom border.[21] The aortic valve plane was identified from dynamic images and by isolation of the zone demarcating alternate count increases and decreases during diastole and systole. The area of the end-diastolic image was obtained by planimetry and the length measured using a sonic digitizing device (Graph-Pen) coupled to a PDP-11/45 computer. The left ventricular end-diastolic volume (EDV) was calculated by the area-length method of Dodge et al.[22] Measurement of end-diastolic volume and left ventricular ejection fraction permitted calculation of left ventricular end-systolic volume (ESV), stroke volume (SV) and cardiac output (CO).

The following list summarizes the hemodynamic measurements made from data obtained during the first passage of tracer through the central circulation.

1. Ejection fraction (EF) (percent) = (EDV counts − ESV counts)/EDV counts × 100.
2. Left ventricular end-diastolic volume (LVEDV) (ml) = $0.85A^2/L$. The radionuclide end-diastolic image was used to obtain the area (A) by planimetry and the length (L) by direct measurement.[21]
3. Stroke volume (SV) (ml) = LVEDV × EF.
4. End-systolic volume (ESV) (ml) = LVEDV − SV.
5. Cardiac output (CO) (liters/min) = SV × HR.
6. Pulmonary transit time (PTT) (seconds) = left atrial mean transit time − pulmonary arterial mean transit time.
7. Pulmonary blood volume (PBV) (ml) = (CO/60) × PTT.
8. Pulmonary blood volume index (PBVI) (ml/m^2) = PBV/Body surface area (m^2).
9. Stroke work (SW) (g-m). This calculation is made indirectly from the following equation[19]:

$$\frac{13.6 \times P \text{ (mean arterial pressure in mm Hg)} \times CO \text{ (liters/min)} \times R\text{-}R \text{ interval (s)}}{60 \text{ s/min}}$$

Measurements and statistical analysis: Student's paired *t* test was used to analyze the differences at rest and during exercise of each measurement in individual subjects before

and after training. In addition, the statistic was applied to compare measurements at rest and during maximal exercise in each subject before and after training. Data were considered significant at the level of $p < 0.05$.

Results

All subjects completed the radionuclide angiocardiogram at rest and during exercise before and after training without difficulty. The resistance of the bicycle ergometer during the last 2 minutes of maximal exercise was 8 newtons. Pedal frequency was unrestricted over each 10 minute session. Mean distance traversed during exercise before training was 4.3 ± 0.42 km and after training was 4.8 ± 0.47 km ($p < 10^{-8}$).

Hemodynamic data: Figure 1 summarizes the hemodynamic data for all subjects at rest and during maximal exercise before and after training. The direction of hemodynamic change from rest to exercise was the same before and after exercise conditioning, but the magnitude of change in several variables was influenced by exercise conditioning. The mean heart rate increased 150 percent from rest to exercise before training ($p < 10^{-9}$); after training, it increased 197 percent from rest to exercise ($p < 10^{-9}$). The mean arterial blood pressure increased significantly from rest to exercise during both testing periods ($p < 10^{-9}$ before and $p < 10^{-8}$ after). The corresponding increase from rest to exercise in cardiac output before and after training was 270 and 379 percent, respectively ($p < 10^{-9}$ and $p < 10^{-8}$). Pulmonary blood volume index increased from rest to exercise both before and after training. Before training, ejection fraction increased from a mean of 0.73 ± 0.06 at rest to 0.87 ± 0.04 during exercise ($p < 10^{-7}$) (19 percent increase). After training, mean ejection fraction at rest was lower (0.67 ± 0.07), and increased by 28 percent to 0.86 ± 0.05 ($p < 10^{-5}$) during maximal exercise. Left ventricular stroke volume increased from rest to exercise in both the pretraining ($p < 10^{-6}$) and posttraining ($p < 10^{-7}$) states. Moreover, the mean end-diastolic volume before conditioning increased from 133 ± 35 ml at rest to 167 ± 40 ml during exercise ($p < 0.002$). After the 6 month training interval, mean end-diastolic volume rose from 167 ± 40 ml at rest to 204 ± 39 ml during exercise ($p < 0.0005$). Figure 2 compares the heart rates at rest and during exercise before and after training. Training decreased the heart rate at rest from 74 ± 11 to 61 ± 7 ($p < 10^{-4}$), but it did not alter the maximal heart rate achieved during studies at peak exercise.

Cardiac output and ejection fraction: Figure 3 compares values for cardiac output at rest and during exercise before and after training. Cardiac output at rest decreased from 6.9 ± 1.1 liters/min before training to 6.7 ± 1.1 liters/min after training (difference not significant). In contrast, the cardiac output achieved during maximal exercise increased from 25.5 ± 5.7 to 32.1 ± 8.7 liters/min after exercise training ($p < 0.02$). The mean increase in exercise cardiac output after training was 21 percent. The largest cardiac output measured after training was 56.6 liters/min. This very large cardiac output was achieved at extreme exertion by a silver medalist in the Olympics. Exercise training decreased the mean ejection fraction at rest from 0.73 ± 0.06 to 0.67 ± 0.07 ($p < 0.0006$) (Fig. 4), but it did not

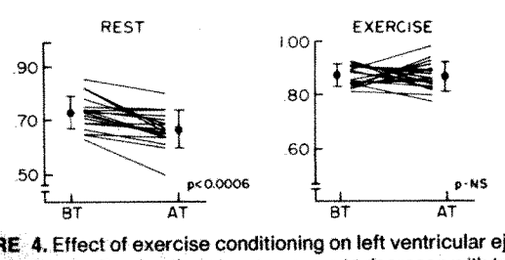

FIGURE 4. Effect of exercise conditioning on left ventricular ejection fraction. The ejection fraction at rest appears to decrease with training, although there is no increase in ejection fraction during maximal exercise. BT = before training; AT = after training. Symbols as in Figure 1.

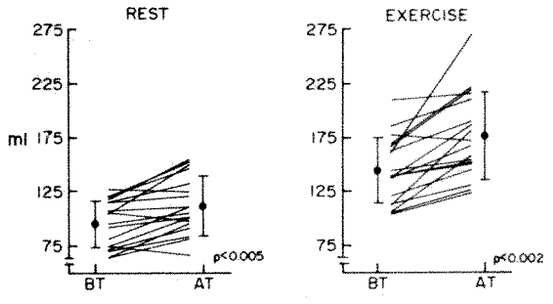

FIGURE 5. Effects of exercise conditioning on stroke volume. Stroke volume at rest and during exercise is increased by training. BT = before training; AT = after training. Symbols as in Figure 1.

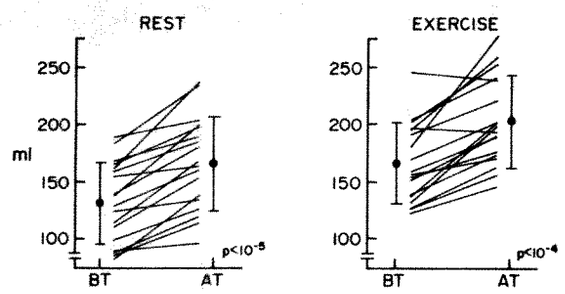

FIGURE 6. End-diastolic volume at rest and during exercise before (BT) and after (AT) training. The mean end-diastolic volume at exercise before training is almost identical to the end-diastolic volume at rest after training. This reflects the left ventricular dilatation occurring with exercise conditioning. Symbols as in Figure 1.

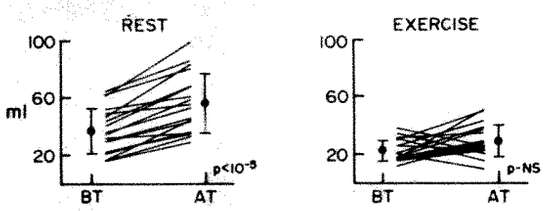

FIGURE 7. End-systolic volume at rest and during exercise before (BT) and after (AT) training. Volume is significantly increased at rest after training; however, there is no significant change during exercise after training. Symbols as in Figure 1.

alter the mean ejection fraction achieved during maximal exercise. Individual variation occurred within the group, and certain athletes appeared to have a greater increase in ejection fraction during exercise than would occur by chance. Stroke volume at rest increased from 95 ± 22 to 112 ± 26 ml after training ($p < 0.005$). Stroke volume at maximal exercise increased from 144 ± 31 to 176 ± 39 ml after conditioning ($p < 0.002$) (Fig. 5).

Ventricular volumes: After training, the end-diastolic volume increased from 133 ± 35 to 167 ± 40 ml at rest ($p < 10^{-5}$) and from 166 ± 34 ml to 204 ± 39 ml during maximal exercise ($p < 10^{-4}$). Because of the cardiac dilatation induced by exercise conditioning the resting end-diastolic volume after training was similar to the end-diastolic volume before training during maximal exercise (Fig. 6). The end-systolic volume at rest increased with training ($p < 10^{-5}$), but the value during maximal exercise remained constant after conditioning (Fig. 7).

Pulmonary and total body blood volumes: Pulmonary blood volume (Fig. 8) increased at rest and during exercise after training ($p < 0.01$ and $p < 0.009$, respectively). Moreover, total body blood volume at rest increased 31 percent from 8.7 ± 0.8 to 11.4 ± 2.2 liters after training ($p < 0.03$) (Fig. 9). A corresponding increase in exercise total body volume from 8.0 ± 0.9 to 10.8 ± 2.3 liters was noted after training ($p < 0.03$).

Stroke work: No significant change occurred in stroke work at rest or during exercise in the post-training state. The stroke work at rest was 176 ± 47 g-m before training and 170 ± 28 g-m after training (Fig. 10). However, the cardiac work per minute at rest decreased from 12.7 ± 2.7 to 9.8 ± 1.9 kg-m/min after training ($p < 10^{-4}$) (Fig. 11). The stroke work during exercise before training was 418 ± 104 and 466 ± 139 g-m after training. This mean stroke work increase of 48 g-m during exercise after training was not significant by the paired *t* statistic (Fig. 10). However, the work per minute during maximal exercise increased from 77.1 ± 18.9 to 84.9 ± 28.2 kg-m/min after training ($p < 0.04$) (Fig. 11). Moreover, comparison of the change in stroke work as a function of end-diastolic volume suggests that the heart works at an increased volume after exercise conditioning (Fig. 12).

Cardiac output by indicator dilution versus volumetric approach: The radionuclide injection permits calculation of cardiac output by two independent approaches. Comparison of cardiac output calculated from the indicator-dilution principle and the volumetric approach produced a correlation coefficient between the two methods of 0.71 at rest and 0.94 during exercise (Fig. 13). Although the absolute magnitude of differences was similar at rest and during exercise, the larger values for cardiac output at high levels of exercise made the rela-

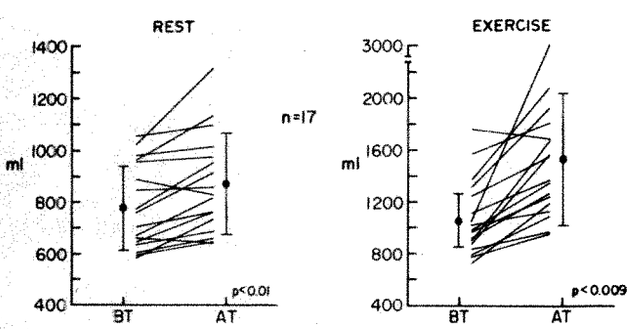

FIGURE 8. Pulmonary blood volume at rest and during exercise before (BT) and after (AT) training. There is a significant increase that suggests an increase in volume within the central circulation as a whole. n = number of subjects. Symbols as in Figure 1.

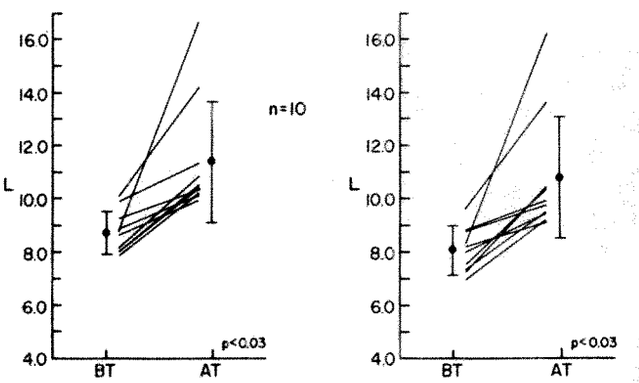

FIGURE 9. Total body blood volume at rest and during exercise before (BT) and after (AT) exercise conditioning. Values at rest and during exercise showed a significant increase after training. This finding suggests that an increase in central circulating blood volume occurs only with an increase in total body blood volume. Symbols as in Figure 1.

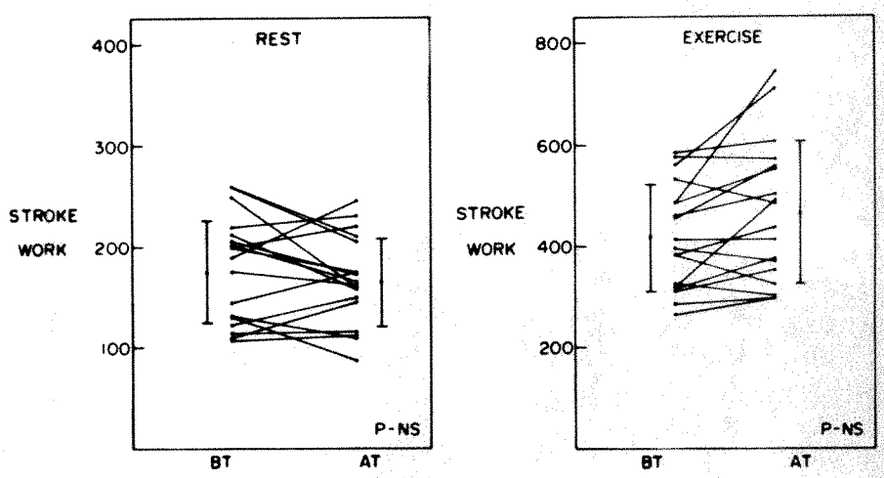

FIGURE 10. Stroke work (g-m) at rest and during exercise before (BT) and after (AT) training. The changes with conditioning are not significant. Symbols as in Figure 1.

tive differences less, causing a more favorable correlation coefficient for exercise measurements.

Discussion

Historical background and methodology: Since the introduction of radioactive tracers by Blumgart and Yens[23] in 1927, widespread use of isotopes in clinical physiology and cardiology has enhanced the understanding of the cardiopulmonary circulation in health and disease. Prinzmetal et al.[24] in 1949 recorded passage of radioactive material through the heart using a Geiger counter. Use of nondiffusable radioactive tracer by Shipley et al.[16] permitted the determination of cardiac output without arterial sampling. Huff and et al.[25] in 1957 used data obtained from four detectors over the chest to calculate central transit times and blood volume. Development of the gamma camera provided a sequential pictorial display of the intracardiac passage of radionuclides.[26–28] Over the past 2 years, further refinement of instrumentation and data processing has led to a broader understanding of the effects of exercise on normal subjects and patients with heart disease.[12,13] Multigated techniques using equilibrium of technetium human serum albumin within the central circulation have been the most popular for evaluation of left ventricular function at rest and exercise.[12,29,30]

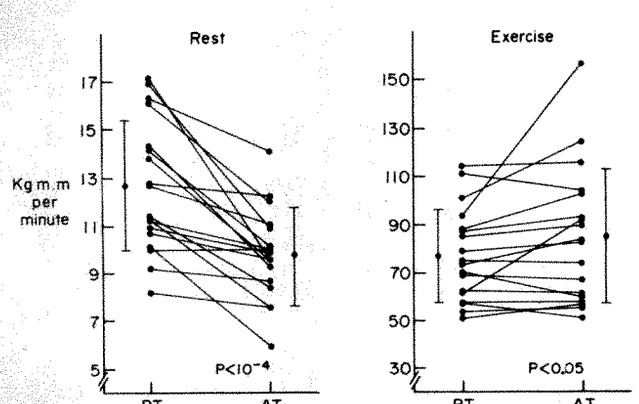

FIGURE 11. Cardiac minute work at rest and during exercise before (BT) and after (AT) physical conditioning. Cardiac minute work is significantly decreased at rest and increased during exercise after training. This finding suggests that the heart is conserving energy at rest to prepare for maximal work at exercise. Symbols as in Figure 1.

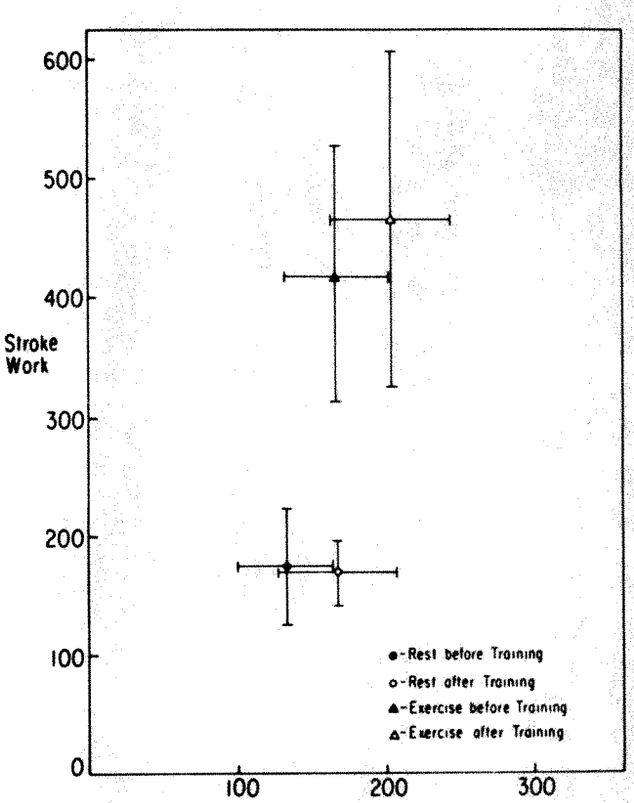

FIGURE 12. Effects of training on the relation between stroke work (g-m) and left ventricular end-diastolic volume (ml). Left ventricular performance is enhanced during exercise by an increase in both stroke work and end-diastolic volume.

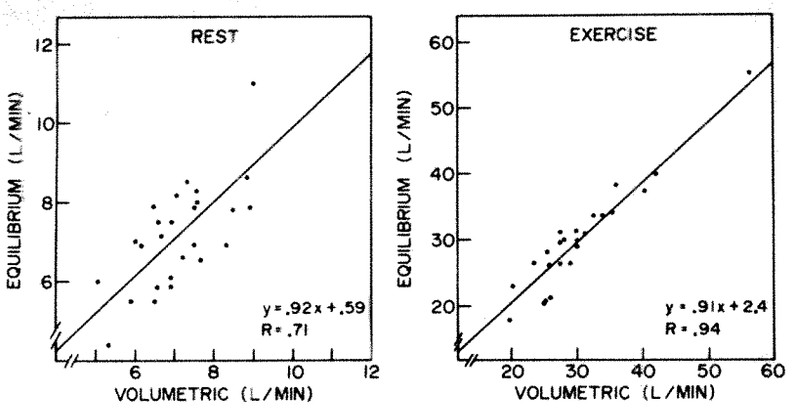

FIGURE 13. Cardiac output calculated from a single radionuclide injection shows a reasonable correlation between the volumetric and indicator-dilution (equilibrium) methods of data analysis over a wide range of cardiac output values at rest and during exercise.

The radionuclide approach used in this study derived data from an initial passage of tracer through the central circulation, a method commonly called the first transit technique. This approach provides several hemodynamic measurements in addition to measurement of left ventricular ejection fraction. End-diastolic volume is obtained by using the prolated ellipsoid model of revolution described by Dodge et al.[22] Cardiac output is then obtained from the volumetric calculation of the stroke volume and the recorded heart rate during injection. The validity of this technique has been documented in a separate publication.[13] Further studies performed in this laboratory in awake mongrel dogs demonstrated the accuracy of left ventricular minor axis dimensions and end-diastolic volumes using the planimetry technique compared to implanted endocardial sonar crystals at heart rates ranging from 60 to 220 beats/min.[21] The volumetric determination of cardiac output in this study compared favorably with measurements obtained by a totally different but more standard method of precordial equilibration isotope-dilution curves described by previous investigators.[15–17] In a separate study, reproducibility of all hemodynamic measurements at rest and exercise was documented by serial studies on the same group of subjects.[31]

The effects of dynamic exercise on the central circulation in normal erect human subjects have frequently been studied during the past two decades. Augmentation of cardiac output with exercise has been shown to result from a large increase in heart rate and a moderate increase in stroke volume.[32–36] However, few data are available that describe potential mechanisms by which intensive training increases cardiac output. Moreover, no data exist documenting changes in ejection fraction, end-diastolic volume, end-systolic volume and pulmonary blood volume after exercise conditioning.

Holmgren et al.[10] demonstrated that prolonged training increases the maximal aerobic capacity and work of the heart. This capacity was determined as the work load on a bicycle ergometer at a pulse rate of 170 beats/min and in a relatively steady state. Several investigators[11,30,37] have ascribed the large cardiac work capacity of athletes to a greater average total body blood volume and total amount of circulating hemoglobin.

Mechanism of increase in maximal cardiac output after exercise training: The experimental design of this study provided a thorough longitudinal examination of hemodynamic changes that occur in well trained collegiate athletes during intensive swimming training over a 6 month period. The purpose was to elucidate the mechanism that permits an increase in the maximal cardiac output achieved after exercise training. Before intensive training, athletes increased cardiac output from rest to exercise primarily by increases in heart rate and stroke volume. In addition, they manifested a modest increase in left ventricular ejection fraction and end-diastolic volume. This study revealed a significant decrease in heart rate at rest and ejection fraction after training. Earlier investigators[38] have established that this reduction in heart rate is secondary to increased vagal tone. Therefore, the decrease in myocardial contractility and heart rate at rest is compensated for by a significant increase in end-diastolic volume in order to maintain the cardiac output at rest at the same level before and after training. This mechanism appears to be a more efficient means for the preservation of a basal cardiac output at a reduced heart rate.[39] The stroke work at rest remained constant in these subjects after training, and the slower heart rate resulted in a constant cardiac output with less minute work.

Although pedal frequency and distance were not controlled during the exercise, resistance levels in newtons and duration of exercise were held constant. This method provided each athlete a competitive goal to attain maximal exertion by the total distance traversed. Maximal exercise after training was accompanied by an increase in cardiac output and by a mean increase of 0.5 km in distance that each subject traversed on the bicycle ergometer during the 10 minute exercise period. The heart rate during maximal exercise was not significantly changed after training. Although stroke volume increased significantly during maximal exercise after training, the end-diastolic volume increased; thus, the maximal ejection fraction achieved did not change from the pretraining state. The cardiac work per minute during maximal exercise was increased after training because of the combined increase in heart

rate and stroke work, which was not sufficient to be significant when considered independently.

Role of increased end-diastolic volume at rest after exercise training: These data emphasize the hemodynamic importance of the increase in end-diastolic volume at rest after training. Moreover, the acute increase in end-diastolic volume in response to exercise stress appears to be an important mechanism for increasing cardiac output before and after training. The greatest magnitude of increase in this variable occurred after training, and this increase appeared to be the primary mechanism of the increase in cardiac output observed during maximal exercise after training because the heart rate was not altered from preconditioning values. Therefore, training increases the capacity of the heart to utilize the Frank-Starling mechanism to increase its effectiveness at rest and during periods of maximal cardiac output.[14] Our study also suggests that increased left ventricular volume after training is accompanied by increases in pulmonary blood volume and total body blood volume.

In conclusion, increased cardiac output during maximal exercise seen after intensive physical training results primarily from the ability of the left ventricle to dilate from rest to exercise and to eject fully this further increase in end-diastolic volume at approximately the same or a lower heart rate. In addition, the cardiac output at rest is maintained at the same level before and after training, although increased vagal tone decreases the heart rate. This is achieved by a stroke volume increase that appears to be dependent on an increase in left ventricular preload reflected by an increase in end-diastolic volume.

Acknowledgment

We express our appreciation to Coach Donald Easterling of the North Carolina State University swimming team for his cooperation in this study. We also thank Bryce Bates, Sharon Karnash, Charles Baker, Phillip Bounous and Thomas Moore for technical assistance and Vanessa Moore for excellent assistance in the final preparation of this manuscript.

Statistical Comparison of M Mode and Two Dimensional Echocardiographic Diagnosis of Flail Mitral Leaflets

GARY S. MINTZ, MD
MORRIS N. KOTLER, MD, FACC
WAYNE R. PARRY
BERNARD L. SEGAL, MD, FACC

Philadelphia, Pennsylvania

Forty-five patients who had surgical therapy for pure mitral insufficiency were evaluated prospectively with both M mode and two dimensional echocardiography; 26 patients (Group I) had a flail mitral valve leaflet, and 19 patients (Group II) had intact chordae tendineae. The M mode echocardiographic criteria of a flail valve (systolic left atrial echoes, systolic mitral valve flutter, diastolic mitral flutter and chaotic paradoxic diastolic posterior leaflet motion) were compared statistically with the two dimensional echocardiographic criterion (loss of systolic leaflet coaptation). The presence of one M mode echocardiographic finding had a sensitivity of 60 percent, a specificity of 53 percent, a predictive accuracy of 63 percent and a predictive value of 50 percent. The sensitivity (96 percent), specificity (84 percent), predictive accuracy (89 percent) and predictive value (94 percent) of the two dimensional echocardiogram were statistically superior to those of the M mode study ($p < 0.05$ or better for each criterion). Thus, two dimensional echocardiography is distinctly superior to M mode echocardiography in the diagnosis of flail mitral valve leaflets.

The M mode and two dimensional echocardiographic features of a flail mitral leaflet have been reported.[1–7] M mode criteria include systolic intracavitary left atrial echoes,[1] systolic mitral valve flutter,[2] course diastolic anterior mitral leaflet flutter[3] (in a flail anterior leaflet), and either paradoxical and chaotic diastolic posterior leaflet motion[4] or early diastolic posterior leaflet flutter[5] (in a flail posterior leaflet). The two dimensional echocardiographic criterion[6,7] is motion of the affected leaflet tip beyond the line of mitral valve closure. However, there have been no studies that have attempted a statistical analysis of both techniques in the diagnosis of a flail mitral leaflet. The purpose of this paper is to report the prospective statistical analysis of the M mode and two dimensional echocardiographic criteria of flail mitral valves.

Methods

Patients: The analysis of the M mode and two dimensional echocardiographic data on all patients at this institution undergoing surgical correction of pure mitral insufficiency forms the basis of this report. Patients with mitral stenosis or combined mitral stenosis and insufficiency and patients with pure mitral insufficiency but no surgical inspection of the mitral valve were not included. Patients with echocardiographic findings of ruptured chordae without surgical confirmation were also excluded. During a 2 year period, 45 patients underwent surgical therapy for pure mitral insufficiency. Twenty-six patients (Group I) had the anatomic finding of ruptured chordae tendineae; the 19 patients (Group II) who had intact chordae tendineae served as control subjects for this study.

M mode echocardiographic studies: Echocardiograms were performed with the patient in the supine or left lateral decubitus position and use of a Smith-Kline/Ekoline 20A ultrasonoscope interfaced with an Irex 101 Continutrace

From the Likoff Cardiovascular Institute, Hahnemann Medical College and Hospital, Philadelphia, Pennsylvania. Manuscript received July 9, 1979; revised manuscript received and accepted September 18, 1979.

Address for reprints: Gary S. Mintz, MD, Cardiovascular Institute, Hahnemann Medical College and Hospital, 230 North Broad Street, Philadelphia, Pennsylvania 19102.

recorder or use of an Irex System II ultrasonoscope and recorder. All studies were performed using a 2.25 megahertz medium (7.5 cm), internally focused transducer. Slow and fast scans from the aorta to below the level of the mitral leaflets were performed in each patient. Large scale mitral valve echograms of all possible portions of the valve were recorded in each patient in order to facilitate analysis of leaflet motion.

Two dimensional echocardiographic studies: These studies were performed using either a Grumman Health Systems RT-400 or a Varian V-3000 phased array sector scanner. The integrity of the mitral valve apparatus was evaluated using the longitudinal, apical and right anterior oblique equivalent views.[8] The study was considered positive if one of these three views showed consistent loss of systolic mitral leaflet coaptation.

Short axis views through the level of the mitral valve leaflets were also performed to detect the presence of mitral stenosis, a cleft anterior mitral leaflet or a defect in the systolic line of closure.

Analysis of data: Both the M mode and two dimensional echocardiographic studies were performed by the same technician. All studies were reviewed by the two observers. When a positive diagnosis was made on two dimensional but missed on M mode study, the latter study was usually repeated.

The sensitivity, specificity, predictive accuracy and predictive value of both the M mode and two dimensional echocardiographic criteria were calculated as follows:

$$\textit{Sensitivity (percent)} = \frac{\text{True positive (TP)}}{\text{True positive (TP)} + \text{False negative (FN)}} \times 100$$

$$\textit{Specificity (percent)} = \frac{\text{True negative (TN)}}{\text{True negative (TN)} + \text{False positive (FP)}} \times 100$$

$$\textit{Predictive accuracy (percent)} = \frac{TP}{TP + FP} \times 100$$

$$\textit{Predictive value (percent)} = \frac{TN}{TN + FN} \times 100$$

Statistical comparisons were performed using either the chi square or McNemar tests.

Results

M mode echocardiographic findings: The M mode findings in 26 patients with a surgically proved flail valve (Group I) are tabulated in Table I. At least one finding of ruptured chordae tendineae (Fig. 1) was observed in 15 patients, including 5 of the 12 patients with a flail anterior leaflet and 10 of the 13 patients with a flail posterior leaflet (1 patient had a technically inadequate study). Ten patients had none of these findings; 2 of them had only holosystolic mitral prolapse, and 8 had a normal mitral valve.

The M mode echocardiographic findings in 19 control patients with intact chordae tendineae (Group II) are listed in Table II. Nine of these patients had at least one finding of a flail valve (Fig. 2).

Two dimensional echocardiographic findings: Two dimensional echocardiography detected a flail

leaflet in 25 of 26 patients who had ruptured chordae tendineae at operation ($p < 0.005$ compared with M mode echocardiography). In each patient there was loss of systolic leaflet coaptation and no chordae were seen to attach the tip of the involved leaflet to the papillary muscles (Fig. 3). Technically it was important to "rock" the transducer back and forth to scan the entire mitral valve commissure in each view. Occasionally, the leaflets appeared normal in one plane and abnormal in another.

There was loss of normal leaflet coaptation in 3 of the 26 control patients (Cases 42 to 44). In one of these patients, elongation of the chordae due to myxomatous degeneration produced the pattern of a flail leaflet; in the other two patients immobility of the posterior leaflet, secondary to the chordal retraction of rheumatic

Two dimensional echocardiographic diagnosis	25	16	3	1	96%	84%	89%	94%

* One patient had a technically inadequate study; data in only 44 patients are tabulated.
† Only patients with a flail posterior leaflet (PML) are included; patients with rheumatic disease are excluded.
FN = false negative; FP = false positive; LA = left atrial; MV = mitral valve; PA = predictive accuracy; PV = predictive value; Sens = sensitivity; Spec = specificity; TN = true negative; TP = true positive.

disease, allowed the anterior leaflet to move beyond the line of closure into the left atrium (Fig. 4). However, these studies were somewhat different from those of typical flail valves; chordae were seen to attach the papillary muscles to the tips of both the anterior and posterior leaflets. No control patient had mitral stenosis as judged from the two dimensional echocardiographic mitral valve area. Three control patients had a cleft anterior mitral leaflet.

Surgical findings: All 26 patients with a flail mitral valve had mitral valve replacement. Three of these had findings of endocarditis and one patient had papillary muscle rupture. Sixteen of the 19 control patients had mitral valve replacement. Three of the 19 had a cleft anterior mitral leaflet and had primary closure of the defect; the findings in the other 16 patients were rheumatic disease (9 patients), papillary muscle fibrosis (4 patients) and myxomatous leaflet degeneration (3 patients).

Statistical analysis: Table III summarizes the true positive, true negative, false positive and false negative M mode and two dimensional echocardiographic find-

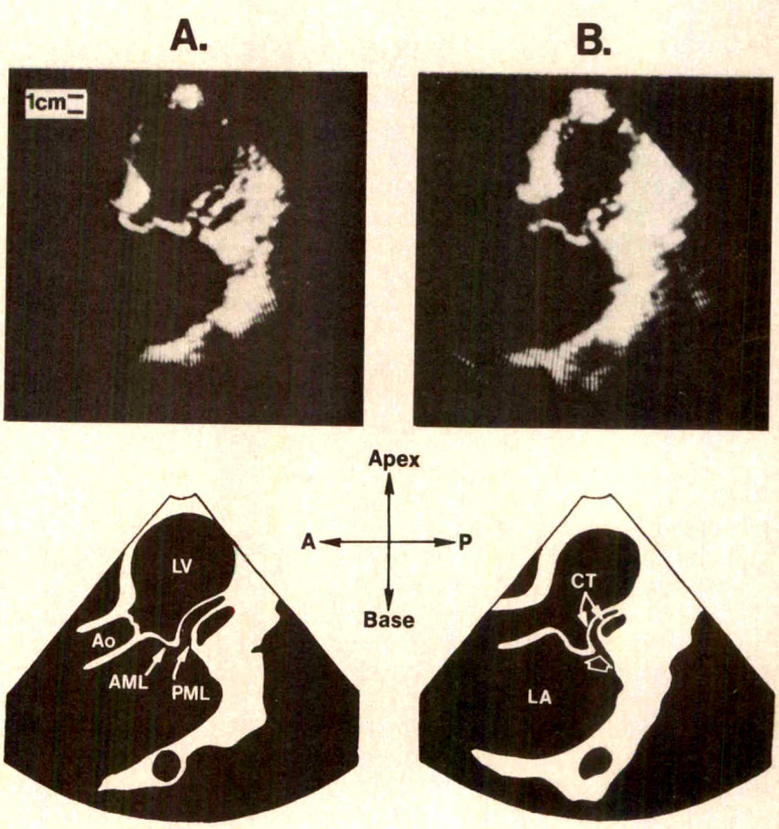

FIGURE 4. Case 42. Diastolic (**A**) and systolic (**B**) frames of a false positive two dimensional echocardiographic study of a flail mitral leaflet. A right anterior oblique equivalent view is presented. Each frame is accompanied by a labeled idealized diagram. The patient had anterior mitral leaflet prolapse with severe mitral insufficiency and intact chordae tendineae. During systole, (**B**), the asymmetrically elongated chordae allowed the tip of the anterior mitral leaflet (AML) to go beyond the tip of the posterior mitral leaflet (PML) into the left atrium (LA) with loss of systolic leaflet coaptation (**open arrow**). However, the chordae tendineae (CT) are continuous from the papillary muscle to the tips of both the anterior and posterior mitral leaflets. Abbreviations as in Figure 3.

ings. The calculated sensitivity, specificity, predictive accuracy and predictive value of the two dimensional echocardiographic study proved superior to the presence of at least one M mode echocardiographic finding of a flail valve ($p < 0.005$, $p < 0.025$, $p < 0.05$ and $p < 0.02$, respectively).

Discussion

Although the M mode and two dimensional echocardiographic findings in patients with flail mitral leaflets are well known, the statistical accuracy of these findings had not been established. In one study of 11 patients with flail leaflets, Humphries et al.[5] found that each patient's M mode echogram showed systolic left atrial echoes, coarse diastolic anterior leaflet flutter, paradoxic diastolic posterior leaflet motion or early diastolic posterior leaflet flutter. In another study of 12 patients, Child et al.[9] found that each had at least one M mode finding of a flail valve. In our study of 45 patients who underwent surgery for pure mitral insufficiency (26 with flail valves and 19 control patients with intact chordae tendineae), two dimensional echocardiography was more sensitive and specific than M mode echocardiography in making this diagnosis.

Patient selection: Only patients who underwent surgery for pure mitral insufficiency were included in our study. Thus, three groups of patients were not included: (1) patients with rheumatic mitral valve disease who had some component of mitral stenosis; (2) patients (including those with mitral valve prolapse) whose angiograms did not reveal mitral insufficiency; and (3) patients with M mode or two dimensional echocardiographic features of a flail valve, but in whom anatomic confirmation was not available.

The strict criteria for the selection of the control patient group served to limit the specificity, predictive accuracy and predictive value of both echocardiographic techniques. If other patients had been added to the control group (for example, those with no angiographic findings of mitral insufficiency or those with mitral stenosis), these values would have been higher. However, it is within the setting of clinical mitral insufficiency that the diagnosis of a flail valve is important, and anatomic visualization must remain the "gold standard."

In approximately 1,500 consecutive studies, we found the two dimensional echocardiographic criteria of ruptured chordae tendineae in only six other patients not included in this report. Four of these six patients underwent neither cardiac catheterization nor valve replacement because of age, other medical problems or patient refusal; two of these patients had mitral valve endocarditis. Two other patients had angiographic evaluation, but the degree of mitral insufficiency was not severe enough to warrant surgery. Although these patients may have had ruptured chordae tendineae, they were not included because of the lack of surgical confirmation.

M mode echocardiographic findings: The sensitivity of the M mode echocardiographic diagnosis of a flail mitral valve was 60 percent. In this series, the M mode echogram seemed more sensitive in detecting a flail posterior than a flail anterior leaflet (72 versus 42 percent), but this difference did not reach statistical significance. The *predictive accuracy* of the M mode study (when one or more of the accepted criteria are present) was 63 percent; 63 percent of all positive findings in patients with significant mitral insufficiency were true positive findings. The *predictive value* of this test was 50 percent; 50 percent of all negative studies in patients with significant mitral insufficiency were true negatives.

The *specificity* of the reported M mode echocardiographic features of flail valves was 53 percent; 47 percent of patients with significant mitral insufficiency and intact chordae had one finding of a flail valve, and 5 percent had two findings of a flail valve.

In the setting of clinical mitral insufficiency, three findings were fairly specific for a flail valve: systolic mitral valve flutter, paradoxic (chaotic) posterior leaflet motion and systolic intracavitory left atrial echoes. In contrast, coarse diastolic mitral valve flutter was nonspecific for a flail valve in the setting of significant mitral insufficiency without stenosis. Eight control patients without a flail valve had diastolic fluttering of one or both leaflets, and three patients with a flail anterior leaflet also had fluttering of the posterior leaflet. Presumably, diastolic mitral valve fluttering can occur in any case of severe mitral insufficiency in which the leaflets are free to vibrate in diastole (not restricted by rheumatic valvulitis).

Two dimensional echocardiographic findings: The *sensitivity* of two dimensional echocardiography in the diagnosis of a flail valve was 96 percent. The *predictive accuracy* was 89 percent; 89 percent of all positive studies in patients with significant mitral insufficiency were true positive studies. The *predictive value* was 94 percent; almost all negative studies in this setting were true negative studies.

The *specificity* of two dimensional echocardiography was 84 percent; 16 percent of patients with significant mitral insufficiency and intact chordae tendineae had a false positive study that indicates a flail valve. In three of our patients the diagnosis of ruptured chordae tendineae was incorrect, but the two dimensional findings suggested the mechanism of mitral insufficiency. In one patient (Case 42) who had the mitral valve prolapse syndrome, asymmetrically elongated chordae tendineae allowed the tip of the anterior leaflet to prolapse beyond the posterior leaflet into the left atrium (Fig. 4). Although the chordae were intact, the anterior leaflet was "functionally flail." In the other two patients (Cases 43 and 44) who had rheumatic mitral insufficiency, the chordae tendineae to the posterior leaflet were thickened and retracted and those to the anterior leaflet were lax. During systole the posterior leaflet remained in a fixed position and the tip of the anterior leaflet overshot the fixed posterior leaflet into the left atrium. We hypothesize that loss of leaflet coaptation from posterior leaflet immobility caused the mitral insufficiency; the valve was "functionally flail." We suggest that these patients may be distinguished from those with true flail

leaflets by detection of chordae attached to the involved leaflet; however, this possibility requires further study.

Implications: Almost all cases of a flail valve are detectable with a two dimensional study whereas only 60 percent have one or more M mode echocardiographic features. M mode echocardiography appears to detect more readily a flail posterior than a flail anterior leaflet. A false positive two dimensional echocardiographic study may occur if the chordae tendineae to the two leaflets are of different lengths because of asymmetric chordal retraction or elongation. Thus, the mitral valve may be "functionally flail" even though the chordae are intact. A false positive M mode study may occur because one of the most sensitive findings, diastolic mitral leaflet flutter, is a sign of severe mitral insufficiency as well as of ruptured chordae tendineae. It is evident from our study that two dimensional echocardiography is statistically superior to M mode echocardiography in the diagnosis of flail mitral valve leaflets.

Complications of the Intraaortic Balloon Counterpulsation Device: Clinical and Morphologic Observations in 45 Necropsy Patients

JEFFREY M. ISNER, MD, FACC
STEVEN R. COHEN
RENU VIRMANI, MD
WALTER LAWRINSON, MD
WILLIAM C. ROBERTS, MD, FACC

Bethesda, Maryland
Washington, D.C.

Of 45 patients who died after insertion of an intraaortic balloon assist device and who were studied at necropsy, 16 (36 percent) were found to have one or more complications (total 20) related to use of the device. The 20 complications consisted of dissection of the aorta or its distal branches, or both (9), arterial perforation (3), arterial thrombi (3), arterial emboli (3), limb ischemia (1) and local wound infection (1). Of the nine cases of arterial dissection, none were diagnosed or suspected before necropsy. Of the entire 20 complications, only 4 (20 percent) were suspected before death. Although the operating team frequently encountered no difficulty at the time of insertion of the device, 12 of the 20 complications were a direct result of insertion of the intraaortic balloon assist device. In two patients in whom insertion of the balloon caused dissection of the aorta, hemodynamic improvement occurred for 2 and 3 days, respectively, even though the "intraaortic" balloon (as well as the catheter) was not located in the true lumen of the aorta. Thus, clinical evaluation of complications related to use of the intraaortic balloon assist device underestimates their frequency. Most complications are consequences of *insertion* of the device, not consequences of its being in place.

Use of the intraaortic balloon assist device for counterpulsation circulatory assistance has gained widespread acceptance. By the end of 1978, its first decade of use, it was estimated that more than 22,000 such devices had been implanted worldwide.[1] Although the balloon device was initially developed and used for treatment of patients with cardiogenic shock,[2–4] its application has been expanded to the prophylactic management of patients with mild and moderate hemodynamic decompensation,[5] and more recently of patients without such decompensation.[6,7] Clinical studies[1,5,6,8–17] have generally estimated that less than 20 percent of patients receiving the intraaortic balloon have complications related to its insertion or use. No systematic necropsy examination of patients undergoing insertion of the balloon has been performed. This report attempts to fill this void by summarizing clinical and morphologic findings in 45 necropsy patients who died after insertion of the balloon.

Study Patients

The records of all patients examined at autopsy from January 1972 through April 1979 at the Clinical Center of the National Institutes of Health and at the Washington Hospital Center were reviewed in a search for patients who had had the intraaortic balloon inserted; data on a total of 33 such patients were retrieved. In addition, the records of 12 necropsy patients from six other medical centers who had had an intraaortic balloon inserted and whose heart and aorta had been

Total	45	64	29–77 (m 55)	32	10	3	1–8 (m 2)	5	4	36	3–34† (m 4)

* Includes two patients in whom the balloon could not be successfully inserted.
† Excludes one patient who survived 115 days after the balloon was removed.
C = complication; CHD = coronary heart disease; D = death; m = mean; Pts. = patients; S = condition stabilized; VHD = valvular heart disease.

examined in the Pathology Branch of the National Heart, Lung, and Blood Institute were retrieved. Thus, a total of 45 necropsy patients who had had an intraaortic balloon inserted and who died within 105 days of the time of balloon insertion form the basis of this report.

The relevant clinical features of the study group are summarized in Table I. The indications for balloon insertion were hemodynamic decompensation in 41 (91 percent) and prophylactic (for coronary bypass surgery) in 4. The balloon device remained in place from 1 to 8 days (average 2). It was removed before death in seven patients; one of the seven survived 105 days after removal of the balloon, and the other six patients from 3 to 34 days (average 15) after its removal.

Results

Aortoiliac dissection: A total of 20 complications were observed in 16 patients (36 percent) (Table II). Dissection of the aortoiliac axis occurred in nine patients (six of whom had dissection for variable distances from the external iliac artery in retrograde direction into the aorta [Fig. 1 to 6]), and in none of the nine patients was the dissection suspected before death (Table II). In four of the nine patients insertion of the device occurred without resistance or other difficulties.

Arterial perforation: This complication was observed at necropsy in three patients: In two, it had been suspected during insertion; in the third patient, no complication of balloon insertion had been suspected clinically but necropsy disclosed a large hematoma in the retroperitoneal area and a perforation in the left common iliac artery.

Antemortem thrombus: This complication, unrelated to underlying atherosclerotic plaques, was found in three patients. In one, thrombus was suspected antemortem because of peripheral emboli. This 50 year old woman received an intraaortic balloon for cardiogenic shock due to acute myocardial infarction. During the 5 days that the device was in place ischemia of the right upper and left lower limbs developed. At necropsy (Fig. 7), there was thrombus lining the aortic intima along the path of the balloon device, as well as infarcts of the spleen and kidney but no thrombus in the heart. Emboli to the right arm in this patient presumably resulted from retrograde perfusion of the transverse aorta during ventricular diastole; emboli causing the splenic and renal infarcts and ischemic left leg probably originated from the mural aortic thrombus and then traveled in anterograde direction during ventricular systole. Necropsy disclosed antemortem thrombus unrelated to underlying atherosclerotic plaque in two other patients: at the bifurcation of the aorta in one patient and in the left leg at the site of balloon insertion in the other (Fig. 8). In neither patient was intravascular thrombus suspected before death. Three additional patients had clinically silent arterial emboli. All five patients with thrombi or emboli had received heparin systemically during the time the balloon had been in place.

Local infection: Necropsy disclosed pus at the site of balloon insertion in one patient. This complication had not been suspected during life. In two other patients in whom the balloon was implanted for septic shock, there was no evidence of seeding in either the balloon catheter or the prosthetic introducer graft.

Type of balloon device: Among the 45 necropsy patients, an Avco type balloon had been utilized in 36 patients (80 percent) and a Datascope type balloon in 9 patients (20 percent). Among the 16 patients with one or more complications, an Avco balloon had been used in 11 (69 percent) and a Datascope balloon in the other 5 (31 percent).

TABLE II

Complications Observed at Necropsy in 16 Patients After Intraaortic Balloon Insertion

Complication	Total	Suspected Due to Insertion	Suspected Before Death	Balloon Insertion "Easy"	Balloon Insertion "Hard"
Arterial dissection	9	9	0	4	5
Aorta and peripheral artery	6	6	0	4	2
Peripheral artery only	3	3	0	0	3
Arterial perforation	3	3	2	0	3
Arterial thrombi	3	0	1	0	0
Arterial emboli	3	0	0	0	0
Ischemic limb	1	0	1	0	0
Local sepsis	1	0	0	0	0
Total	20	12	4	8	8

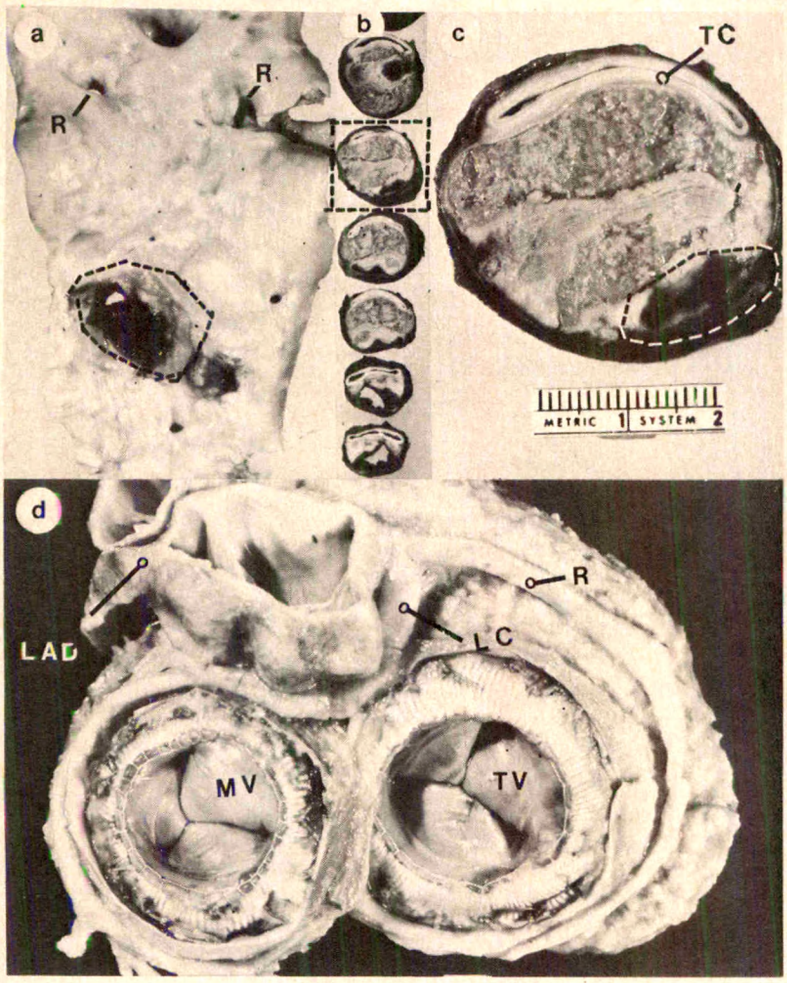

FIGURE 1. Aorta and heart in a 65 year old woman with aortic dissection at the time of insertion of the balloon. **a,** intimal surface of abdominal aorta showing ulcerated atherosclerotic plaque (**dashed circle**) where balloon catheter left the true lumen of the aorta and entered the medial wall of the aorta producing a false channel, cross-sections of which are shown in **b; c** is an enlargement of a section enclosed in the **box** in **b.** The false channel is filled with thrombus that compressed the true channel (TC), virtually closing it. The residual site of the balloon catheter is circled by **broken lines** in **c.** The patient had the balloon inserted intraoperatively because she could not be weaned from cardiopulmonary bypass after replacement of the mitral (MV) and tricuspid (TV) valves with porcine prostheses (**d**). The balloon was removed on the 3rd postoperative day, when she was in hemodynamically stable condition. LAD = left anterior descending coronary artery; LC = left circumflex coronary artery; R = renal artery (**a**) and right coronary artery (**d**).

Complications related to balloon insertion and technical skill: In 35 of the 45 patients the balloon was known to have been inserted by a senior staff surgeon experienced in the technique of balloon insertion. In the other 10 patients it was known only that the balloon had been inserted either by a senior staff surgeon experienced in the technique of balloon insertion or by a surgeon-in-training in cardiovascular surgery under the direct supervision of a senior staff surgeon. Of the 35 patients whose balloon device was definitely inserted by a senior staff cardiovascular surgeon, complications related to the balloon occurred in 12 (34 percent). Of the 10 remaining patients, complications related to the balloon occurred in 4.

Discussion

Factors related to complications: Of the 20 complications (in 16 patients), only 4 (20 percent) had been suspected before death. The mean age of the patients with complications (58 years) was similar (Fisher's exact test) to the mean age of the patients without complications (57 years) (Table III). Although only 16 (36 percent) of the 45 study patients were women, 8 (50 percent) had 11 of the 20 complications. However, the

TABLE III

Factors Related to Balloon Insertion: Patients With Complications Versus Patients Without Complications

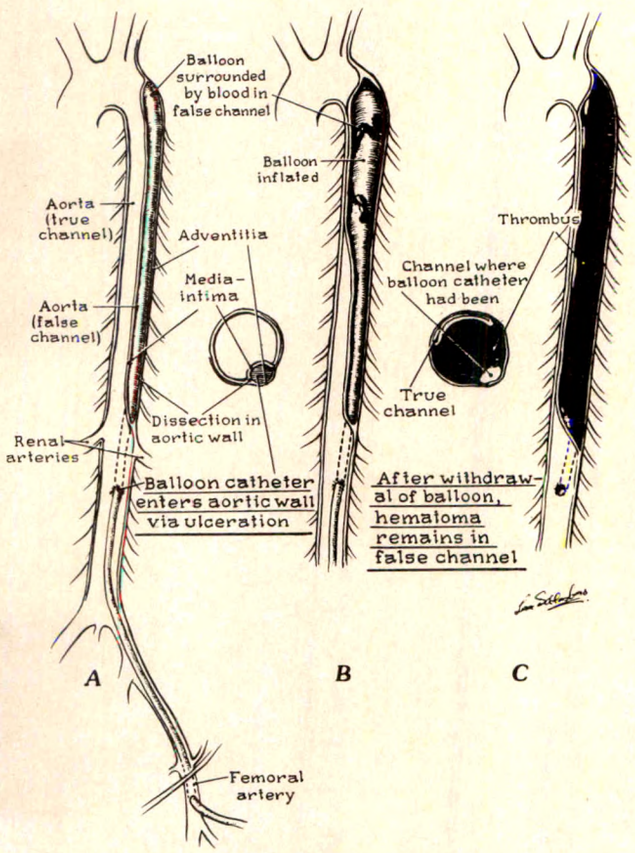

FIGURE 2. Same patient. Drawing of the apparent manner in which dissection was produced in the patient whose aorta is illustrated in Figure 1. **A**, the catheter entered through an ulcerated atherosclerotic plaque in the abdominal aorta and functioned successfully for 3 days even though it was located in the false channel. **B**, after removal of the balloon the patient survived for 28 days, during which time organized thrombus filled the false channel (**C**).

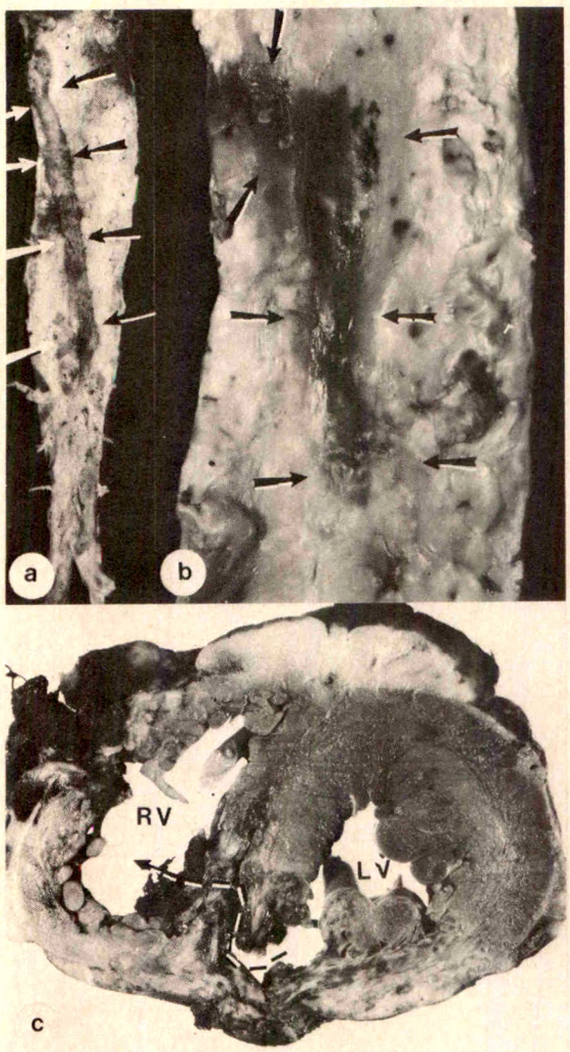

FIGURE 3. Adventitial (**a**) and intimal (**b**) surfaces of the aorta of a 77 year old man who had an intraaortic balloon inserted for shock due to rupture of the ventricular septum (**arrow, c**) after acute myocardial infarction. At necropsy, the balloon (**arrows, a**) could be seen in the false channel through the translucent adventitia; hemorrhage (**arrows, b**) observed on the intimal surface reflected the site of the false channel. LV = left ventricle; RV = right ventricle.

male/female ratio of the groups with and without complications was not significantly different.

Patients with complications were also not distinguished from patients without complications either by the indication for insertion (hemodynamic decompensation was the indication for the vast majority of both groups) or by the underlying cardiac disorder (coronary heart disease was the cause in nearly 75 percent of each group). The number of unsuccessful attempts at insertion did not necessarily predict a complication. However, the proportion of difficulties acknowledged by the operator was greater among the patients with (38 percent) than among those without (17 percent) observed complications. An "easy" insertion did not preclude a complication, and a difficult insertion did not necessarily imply a complication.

Insertion-related complications: Most complications of the balloon appear to result from insertion of the device. Insertion was more difficult and was attended by a higher complication rate in patients undergoing cardiac operations than in patients in whom a surgical procedure was not performed (Table IV). Of 37 attempts at 37 different sites in the 29 operative patients, 11 complications occurred and 8 were related to insertion. In contrast, only one unsuccessful attempt at insertion was made among the 16 nonoperative patients and only three complications were related to insertion.

Frequency of complications: Although the intraaortic balloon is currently a standard therapeutic modality in many institutions, analysis of the morbidity of this device has largely been restricted to clinical observations.[1,5,6,8–19] Such investigations have estimated the frequency of complications of the balloon to be between 0 and 36 percent (average 12 percent).[1,5,6,8–19] There are several reasons why clinical studies may underestimate the true frequency of complications of intraaortic balloon insertion. First, the injury resulting from use of the device may go unrecognized unless it results in a relatively catastrophic clinical consequence.

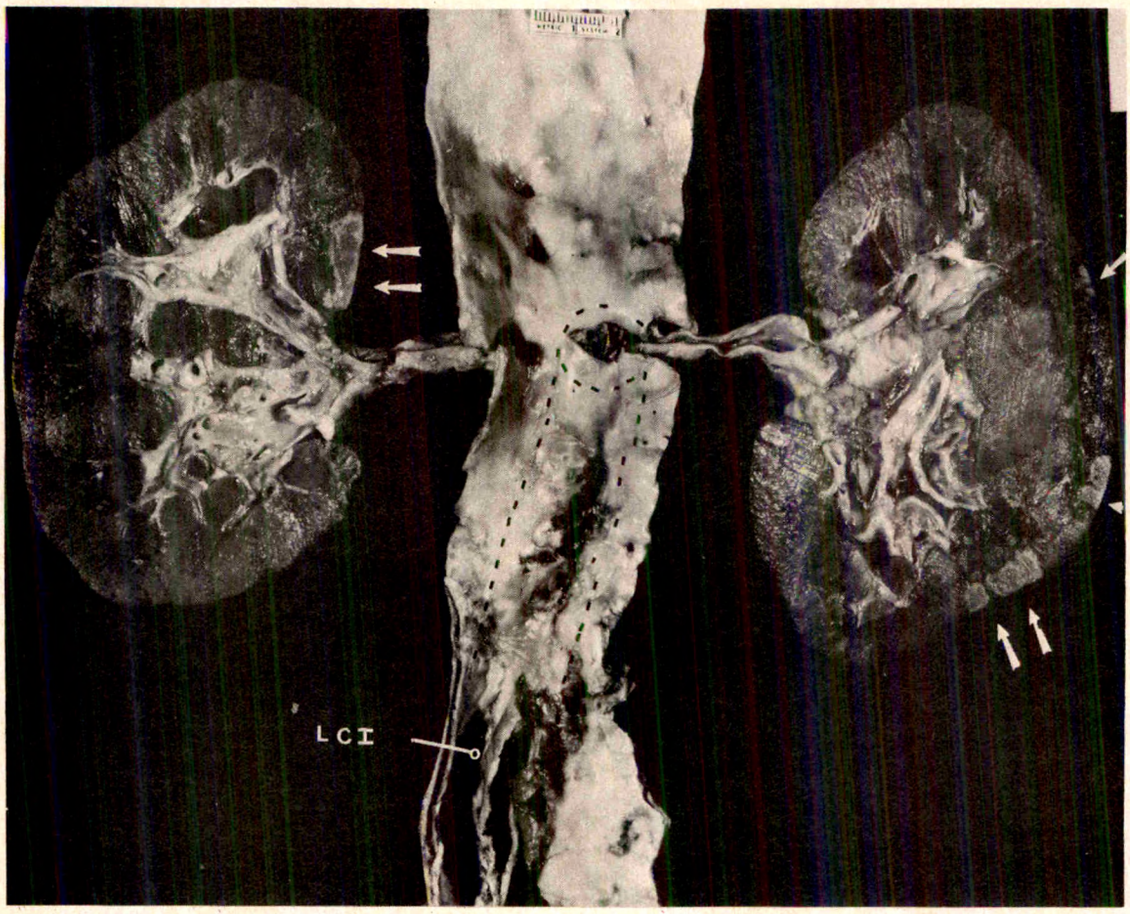

FIGURE 4. Intimal surface of aorta and cut surfaces of both kidneys in a 62 year old man. The left common iliac (LCI) artery and the abdominal aorta are dissected and the false channel (**dashed parallel lines**) is filled with thrombus. The thrombus protrudes above the false channel at its exit site at the level of the renal arteries (**dashed circle**). It appears that part of the thrombus in the false channel dislodged and migrated to small renal arteries of both kidneys producing multiple renal cortical infarcts (**arrows**).

Second, survival after attempted balloon insertion is often short; consequently, there may be inadequate time for the complications resulting from the balloon insertion to evolve into clinically overt signs and symptoms. Third, most studies of complications related to the balloon exclude patients in whom the balloon could not be successfully inserted. The frequency of complications in such patients is likely to be equal to, if not greater than, that in patients in whom balloon insertion was successful, and exclusion of such patients results in a falsely low estimate of total balloon-related complications. Fourth, even those clinical studies in which some clinical observations were confirmed by necropsy may have underestimated the overall frequency of balloon-related complications if they were not looked for specifically.

Recognition of aortoiliac dissection: These problems are best illustrated by the 9 of our 45 patients in whom dissection of the aortoiliac axis was observed at necropsy. In none of the nine patients was dissection suspected, much less recognized, before death, and in two of the nine patients balloons functioned properly for 2 (Fig. 3) and 3 (Fig. 1 and 2) days, respectively, even though they were situated in the false channel. Thus,

TABLE IV

Balloon Insertion Data: Operative Versus Nonoperative Groups

Group	Pts. (n)	Insertion Attempts			Insertion Sites		Insertion Timing			Complications	
		S	U	T	Leg	Aorta	Pr O	IO	Po O	Total	I

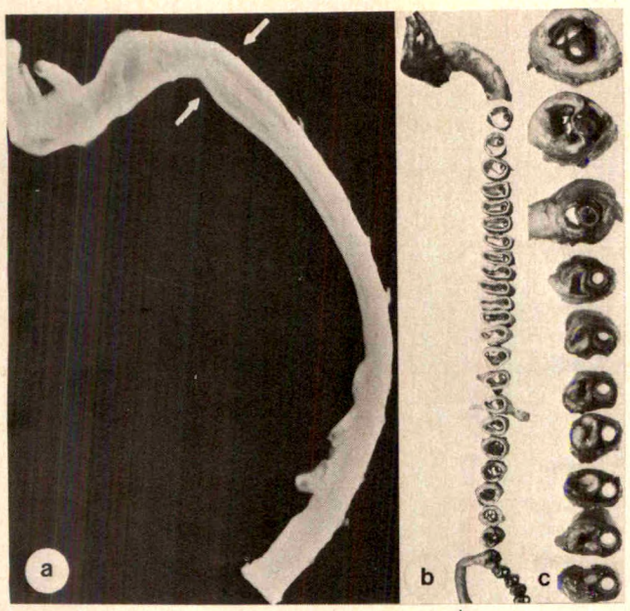

FIGURE 5. Postmortem radiograph (**a**) and cross-sections (**b** and **c**) of the aorta in a 49 year old woman who received the intraaortic balloon for shock after a coronary bypass operation. The aorta was relatively free of atherosclerotic plaques, contained no calcific deposits (as illustrated in **a**) and was judged on gross examination to be normal. However, sections at 1 cm intervals (**b**) disclosed a dissection of the left common iliac artery and the distal portion of the abdominal aorta (**c**). The dissection was not suspected either before death or on initial examination at necropsy.

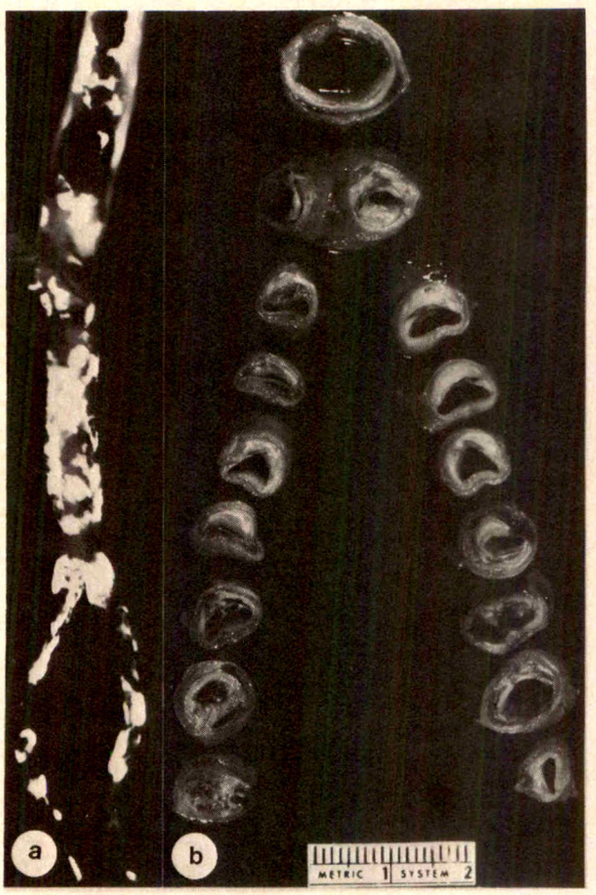

FIGURE 6. Severely calcified atherosclerotic plaques (**a**) in the abdominal aorta and common iliac arteries in a 66 year old woman. The common iliac arteries were severely narrowed by the plaques, which prevented successful insertion of the balloon. Multiple insertion attempts in both lower limbs resulted in dissection of both common iliac arteries (**b**).

without necropsy, none of the nine patients would have been classified as having had a complication. Only three of the nine patients with a dissection survived for more than 2 days after insertion. Wolfson et al.[15] and McEnany et al.[1] have pointed out that there may be a substantial delay in the appearance of clinical signs of dissection (pain, reduction in hematocrit, radiographic abnormalities) despite injury to the arterial wall. Thus, in at least some patients, the limited survival after balloon insertion probably prevented the development of overt clinical signs of dissection that would have allowed clinical recognition of a balloon-related complication.

The nine patients with dissection related to the balloon included two patients in whom the device could not be successfully inserted in at least one leg: In one patient the device ultimately was inserted in the contralateral leg, but in the second patient unsuccessful attempts to pass the balloon through either leg resulted in dissection of both iliac arteries and the abdominal aorta (Fig. 6). This pair of complications (dissections) would have been excluded from some reports because successful balloon insertion was not accomplished.

Furthermore, in three patients aortoiliac dissection was not suspected initially at necropsy from the gross appearance of the aorta and the proximal iliac arteries; only when the aorta, iliac arteries and proximal branches of the iliac arteries were cross-sectioned at 1 cm intervals was the dissection apparent (Fig. 5). Thus, a lack of systematic necropsy examination would have resulted in failure to diagnose dissection of the aortoiliac axis in at least three patients. In those patients in whom the balloon is not in place at necropsy because of its prior removal, systematic examination of the distal aorta, and particularly its distal branches, may not be carried out.

Recognition of arterial perforation: Of the three patients with arterial perforation secondary to balloon insertion, in two the complication was suspected clinically by the surgeon at the time of balloon insertion. The remaining patient survived less than 12 hours after admission for acute myocardial infarction. Balloon counterpulsation had been initiated because of hypotension that persisted and the patient died shortly thereafter. The retroperitoneal bleeding discovered at necropsy had not been suspected during life; this patient's short survival time may not have allowed adequate time to evaluate fully the potential contribution of balloon-related bleeding to the patient's hypotension. In addition, this patient serves to emphasize the difficulty of evaluating complications related to the balloon in patients whose baseline state is itself catastrophic. In the normotensive patient (one receiving the balloon

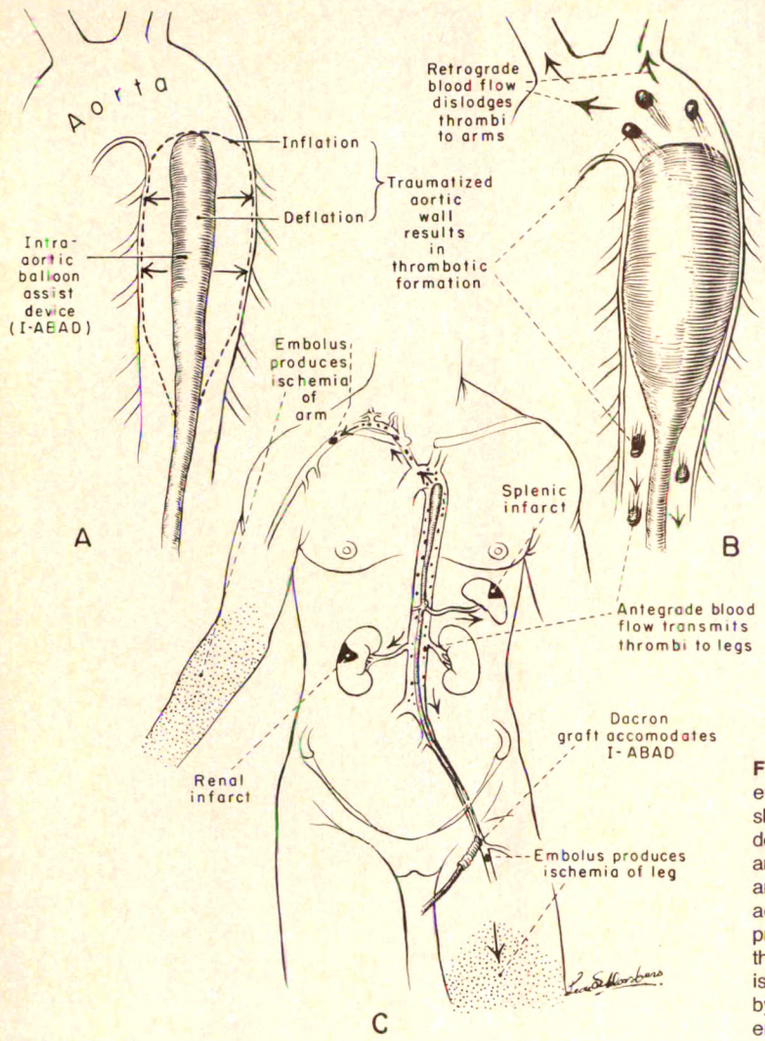

FIGURE 7. Drawing of the presumed pathogenesis of limb ischemia resulting from use of the balloon in a 50 year old woman with shock from acute myocardial infarction. During the 5 days that the device was in place (**A**), the patient had ischemia of the right arm and left leg. At necropsy, there were embolic infarcts of the spleen and right kidney and thrombi adherent to the intimal surface of the aorta along the path of the balloon catheter. (No thrombus was present in the heart.) Emboli from the balloon catheter-induced thrombus along the aortic wall appear to have resulted in right arm ischemia from retrograde perfusion of the proximal arch arteries by the balloon during ventricular diastole (**B**); distal (anterograde) emboli resulted in visceral and left leg ischemia (**C**).

prophylactically, for example) the precipitous onset of hypotension after balloon insertion would presumably be recognized as a catastrophic event. In contrast, in the patient who is hypotensive because of pump failure before balloon insertion, the persistence of hypotension after insertion would not be considered a new catastrophic event; more likely, it would be interpreted as pump failure refractory to counterpulsation.

Recognition of arterial thrombi or emboli: Of the six patients with arterial thrombi or emboli, one who survived 5 days had clinical manifestations that allowed antemortem recognition of these complications (Fig. 7). This patient had thrombus adherent to the aortic intima along the path of the balloon; emboli, almost surely from this thrombus, resulted in clinically recognizable ischemia of the right arm and left leg and clinically silent renal and splenic infarcts. To our knowledge, this is the first patient described in whom arm ischemia appears to have occurred as a result of *retrograde* embolization from an intraaortic balloon. A second patient, who survived less than 24 hours, had a brain-stem embolus and massive intracerebral bleeding that was not diagnosed before death. In this patient, too, the (cerebral) embolus may have resulted from retrograde embolization from the balloon (although no thrombus was found along the aortic wall) because other sources of emboli were absent. The remaining four patients with thromboembolism, two of whom survived less than 48 hours, had no clinical signs suggesting a thrombotic or embolic complication. In the absence of necropsy, none of these patients would have been identified as having a balloon-related complication. However, it is likely that had the woman with a large thrombus at the bifurcation of the aorta survived, ischemia of the leg might well have resulted. Beckman et al.[10] and other investigators[1,18] have emphasized that symptoms of limb ischemia related to balloon insertion may not appear for some time after insertion. Finally, the thrombotic and embolic complications in these six patients all occurred despite use of systemically administered heparin.

The single case of localized wound sepsis also was not suspected before death, again presumably because of a short (12 hours) survival after balloon insertion. Although the balloon and its Dacron® graft introducer

represent two potential niduses for infection, none of our three patients with systemic sepsis had secondary seeding of these two foreign bodies.

Causes of complications resulting from insertion of the balloon: Most previous reports of balloon-related complications diagnosed clinically among large groups of patients have indicated that most complications resulted from obstruction to the arteries supplying blood to the legs[8–10,12,18,19]; less frequently, insertion of the device has been cited as the primary etiologic factor.[1,15] In our patients, 12 of the 20 complications (60 percent) resulted from *insertion* of the balloon. The relatively short duration of survival after balloon insertion may explain why there were not more patients with leg ischemia. If such an assumption is valid, then the frequency of complications among our patients would be even higher than 35 percent. Easy insertion of the balloon does not preclude serious complications: In four patients with dissection of the aorta, the surgeon denied difficulty with insertion, including having to "push hard." Whether the complications result primarily from obstruction to arteries to the legs or from insertion of the device, the ultimate determinant of balloon-related complications in most patients is the *status of the native arteries.* Older age and female sex should theoretically affect in a detrimental way the capability of the native circulation to accommodate the balloon. The caliber of the arteries in women is generally smaller than that in men,[20] and thus their arteries are more difficult to cannulate and are potentially less capable of providing adequate blood flow around the balloon catheter. The older the patient, the greater is the likelihood that atherosclerotic obstructive disease will diminish the amount of lumen available to accommodate the balloon catheter. However, complications of insertion are not restricted to patients with peripheral vascular disease; dissection complicated insertion of the balloon in the patient illustrated in Figure 5 although the aorta and its distal branches were free of significant atherosclerotic plaques.

Insertion of the balloon was more difficult and associated with a greater frequency of complications in patients who underwent cardiac operations than in those who did not. Our finding is contrary to that of Lefemine et al.[9] The reason for the disparate observations is unclear.

Role of type of device: The balloon catheter presently used with the Avco intraaortic balloon assembly is several times stiffer than that manufactured by Datascope. However, of the 20 complications described in this report, 7 (including 4 arterial dissections and 2 arterial perforations) occurred in patients in whom the Datascope device had been used. Therefore, complications, including those related to insertion, do not appear to be simply a function of the type of balloon catheter used by a particular center.

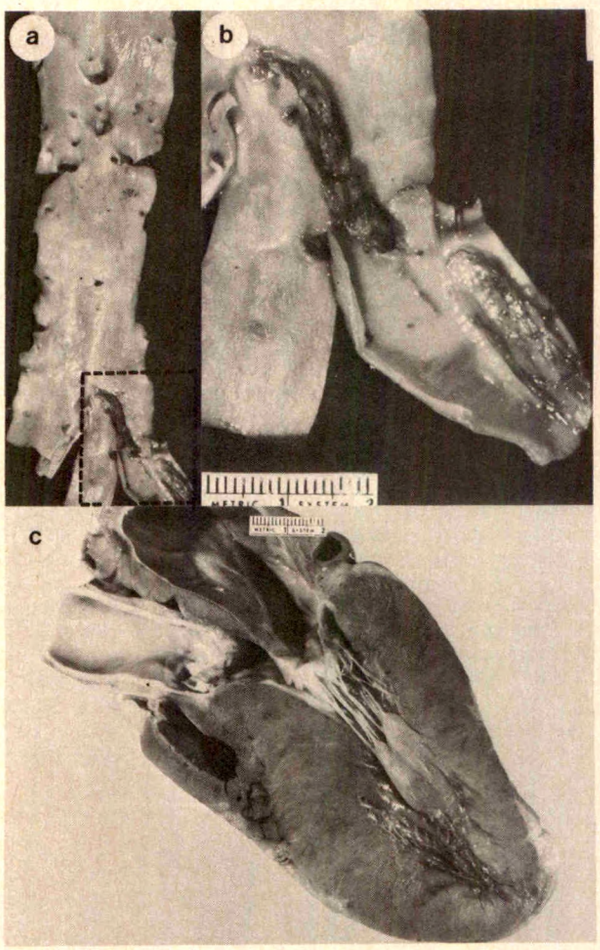

FIGURE 8. Intimal surface of the abdominal aorta and common iliac arteries showing thrombus in the left common iliac artery (**dashed box** in **a**, enlarged in **b**) in a 50 year old man. The thrombus was adherent to both the balloon device and the intima of the left common iliac artery. The balloon produced transient hemodynamic benefit for 2 days before refractory hypotension from hypertrophic cardiomyopathy developed (**c**).

Implications: Our study suggests that previous reports of the frequency of balloon-related complications, based largely on clinical observations, have underestimated the complications of this device. Aortoiliofemoral angiography or Doppler monitoring, or both, has been recommended,[18,21] but apparently not frequently used to assess more optimally the distal arteries housing the balloon device. The addition of a central lumen to the intraaortic balloon catheter to allow pressure monitoring[15] may also help avoid complications related to balloon insertion.

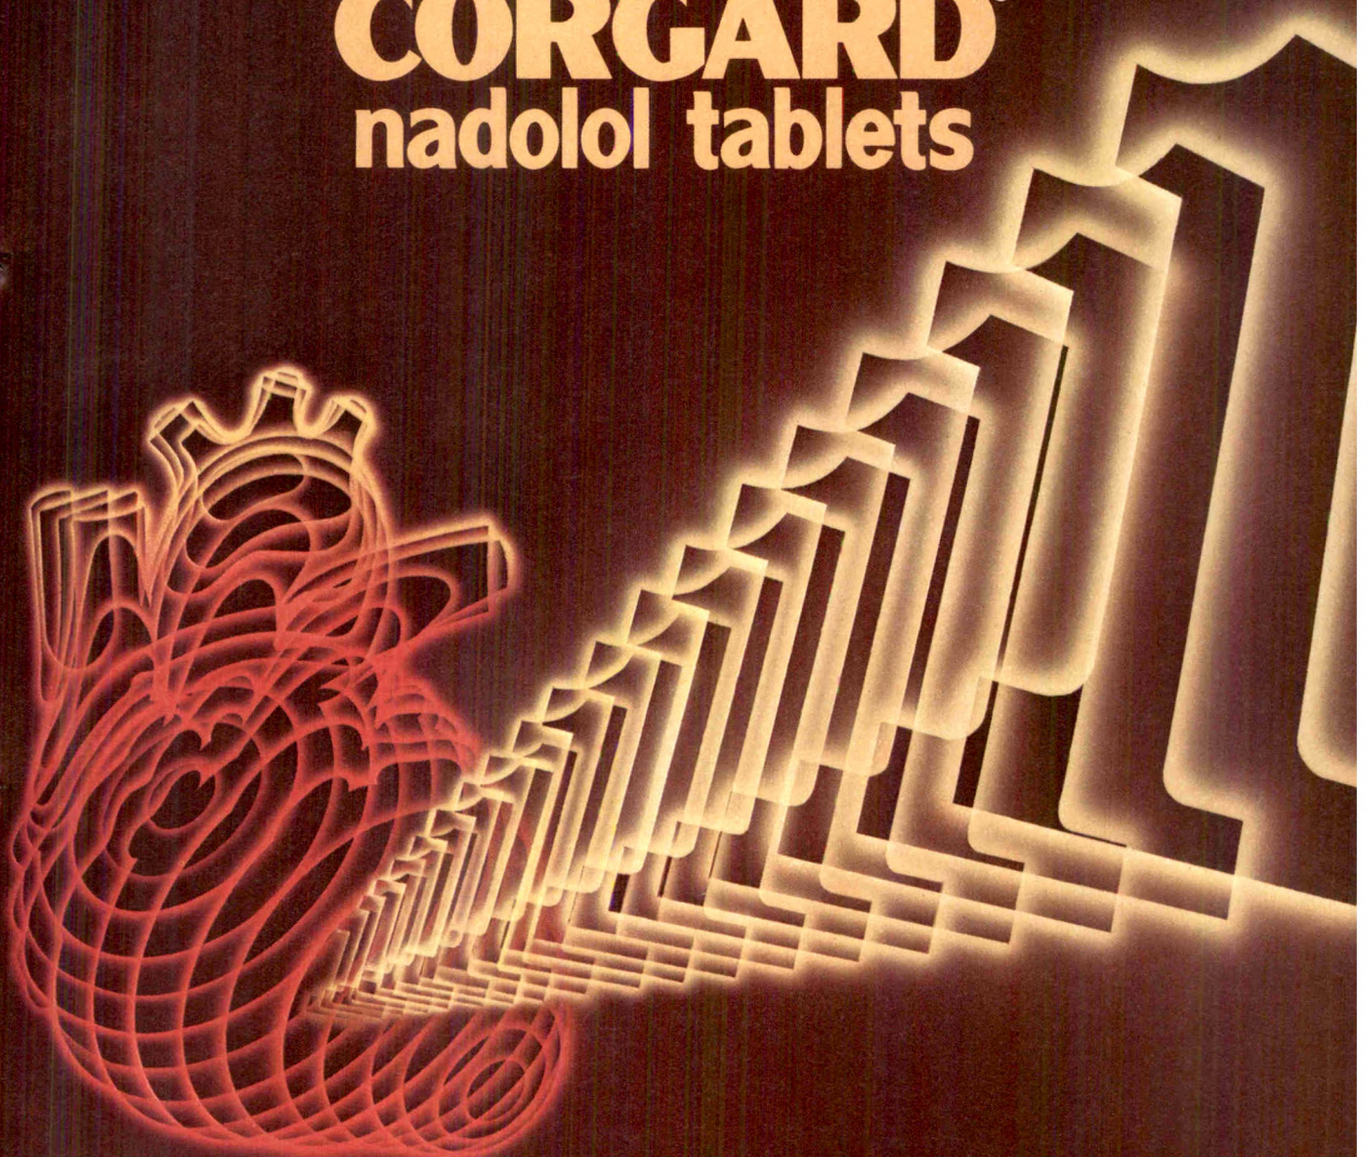
NEW FOR HYPERTENSION

IT HAPPENS ONLY ONCE:

E.R. SQUIBB & SONS, INC., INTRODUCES

CORGARD® nadolol tablets

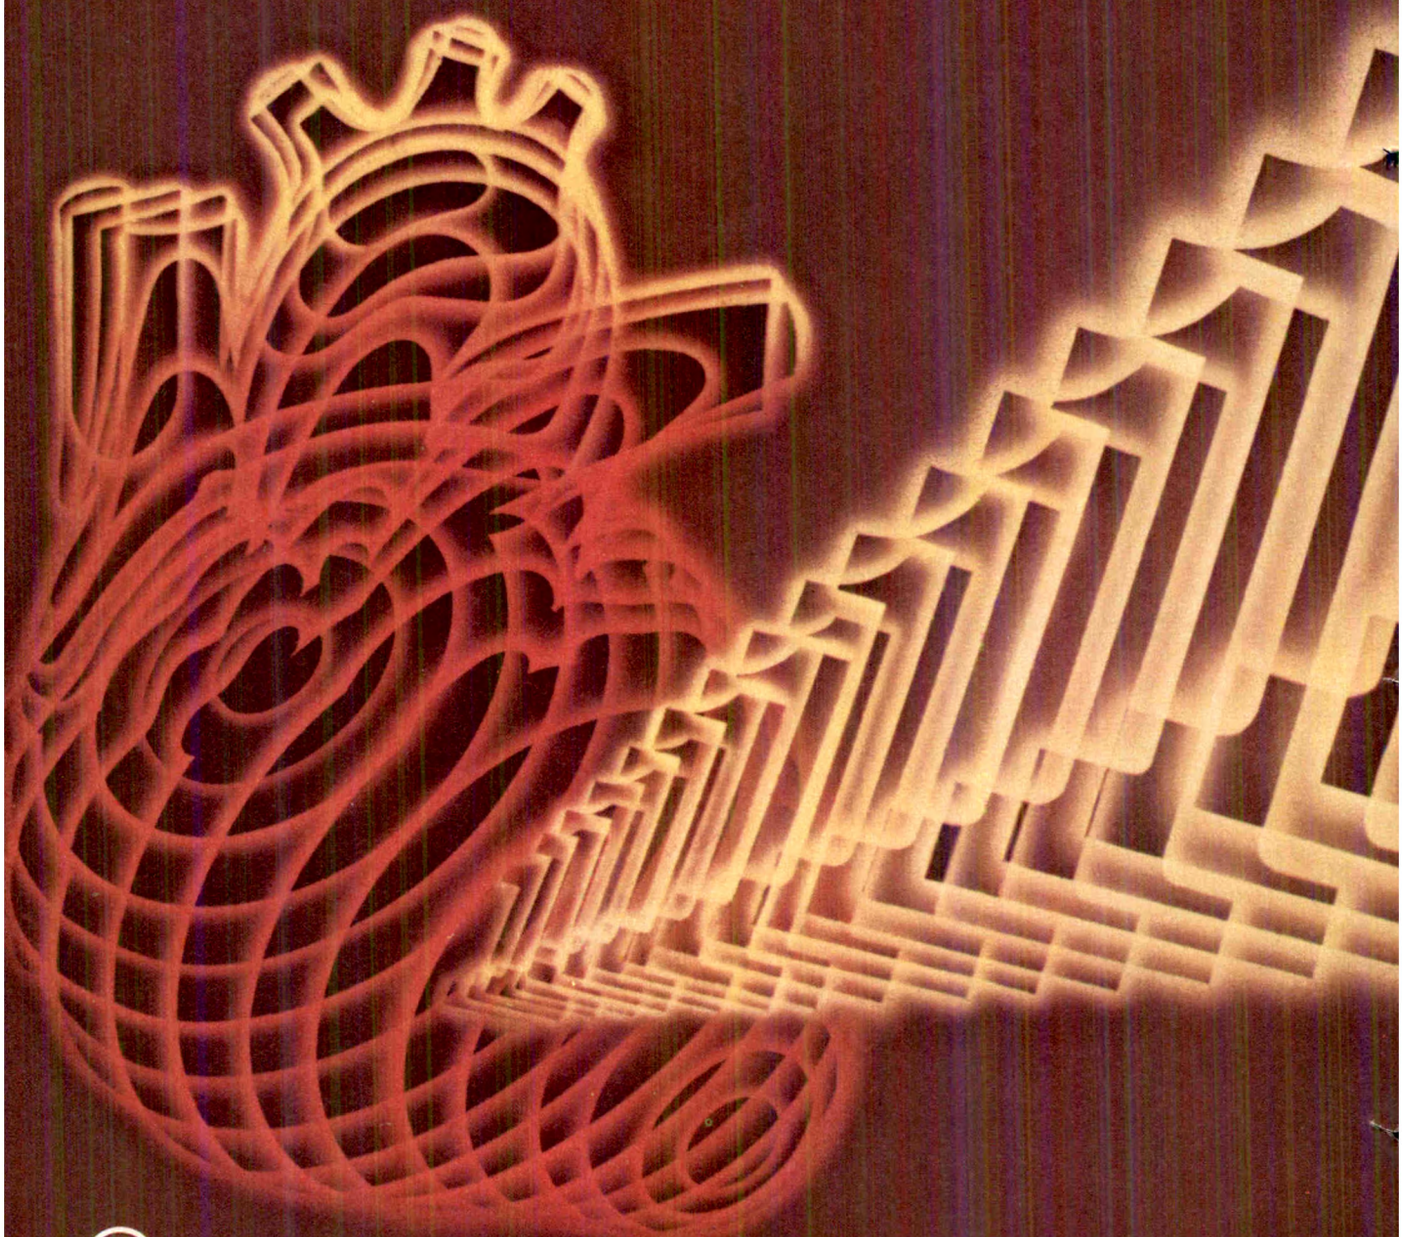


THE FIRST BETA-BLOCKER WITH ONCE-A-DAY DOSAGE

Please see brief summary on last page of this advertisement.

NEW FOR HYPERTENSION

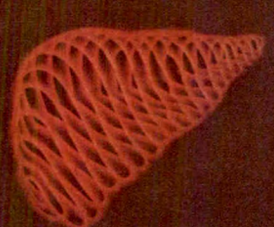
CORGARD® [nadolol tablets] THE FIRST BETA-BLOCKER WITH ONCE-A-DAY DOSAGE



SQUIBB®

CORGARD: OFTEN EFFECTIVE WITHOUT A DIURETIC In 114 hypertensive patients, Corgard, given once a day (without a diuretic), produced significant overall reduction in blood pressure in 94% of the patients—this included 63% of the patients who achieved normalized supine diastolic pressures ($\leq$90 mm Hg).[1]

CORGARD: THE METABOLIC PROFILE MAKES SENSE
Corgard is not metabolized by the liver and is excreted unchanged.



CORGARD: THE LOW INCIDENCE OF SIDE EFFECTS MAKES SENSE Corgard usually does not cause impotence or loss of libido. Orthostatic hypotension is rarely a problem. Pharmacologic heart rate reduction may occur, but is rarely symptomatic. For a full discussion of Contraindications, Precautions, Adverse Reactions, and Warnings, including avoidance of abrupt withdrawal, see brief summary of prescribing information on next page of this advertisement.

CORGARD: THE CONVENIENCE OF ONCE-A-DAY DOSAGE MAKES SENSE
Corgard, once a day, provides 24-hour reduction of blood pressure. And once-a-day dosage makes it much easier for your patients to comply.

THE COMMON-SENSE BETA-BLOCKER

CORGARD®
nadolol tablets

Please see brief summary of prescribing information on next page of this advertisement.

NEW ALSO FOR ANGINA PECTOI

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure—Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery — Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Hepatic or Renal Function — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

Drug Interactions — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking a patients with nadolol plus a catecholamine-depleting ag for evidence of hypotension and/or excessive bradycard vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility toxicologic studies in mice, rats, and dogs, nadolol did r toxic effects. In 2-year oral carcinogenic studies in rats a not produce neoplastic, preneoplastic, or nonneoplastic

Pregnancy — In animal reproduction studies with na embryo- and fetotoxicity was found in rabbits (but not i doses 5 to 10 times greater (on a mg/kg basis) than maxi dose; no teratogenic potential was seen in any of these s well-controlled studies in pregnant women; therefore, us women only if potential benefit justifies potential risk to

Nursing Mothers — It is not known whether this dru milk. Because many drugs are excreted in human milk, nadolol is administered to a nursing woman. Animal stu nadolol is found in the milk of lactating rats.

Pediatric Use — Safety and effectiveness in children h

ADVERSE REACTIONS: Most adverse effects have bee and have rarely required nadolol withdrawal.

Cardiovascular — Bradycardia with heart rates of les minute occurs commonly, and heart rates below 40 bea symptomatic bradycardia were seen in about 2 of 100 p peripheral vascular insufficiency, usually of the Raynau in approximately 2 of 100 patients. Cardiac failure, hyp rhythm/conduction disturbances have each occurred in tients. Single instances of first degree and third degree h reported; intensification of AV block is a known effect c also CONTRAINDICATIONS, WARNINGS, and PRE **Central Nervous System** — Dizziness or fatigue reporte of 100 patients; paresthesias, sedation, and change in be approximately 6 of 1000 patients.

Respiratory — Bronchospasm reported in approximatel (see CONTRAINDICATIONS and WARNINGS). **Gastr** Nausea, diarrhea, abdominal discomfort, constipation, anorexia, bloating, and flatulence each reported in 1 to 5 **Miscellaneous** — Each of the following reported in 1 to rash; pruritus; headache; dry mouth, eyes, or skin; imp libido; facial swelling; weight gain; slurred speech; coug sweating; tinnitus; blurred vision. Although relationship clear, sleep disturbances have been reported. The oculor drome associated with practolol has not been reported w

Potential Adverse Effects: Although other adverse effe other beta-adrenergic blocking agents have not been rep they should be considered potential adverse effects of na **vous System** — reversible mental depression progressing disturbances; hallucinations; an acute reversible syndron disorientation for time and place; short-term memory lo with slightly clouded sensorium; decreased performance psychometrics. **Gastrointestinal** — mesenteric arterial th colitis. **Hematologic** — agranulocytosis; thrombocytope bocytopenic purpura. **Allergic** — fever combined with a throat; laryngospasm; respiratory distress. **Miscellaneou** alopecia; Peyronie's disease; erythematous rash.

OVERDOSAGE: Nadolol can be removed from the gene hemodialysis. In addition to gastric lavage, employ the f appropriate. In determining duration of corrective thera duration of effect of nadolol.

Excessive Bradycardia — Administer atropine (0.25 to no response to vagal blockade, administer isoproterenol

Cardiac Failure — Administer a digitalis glycoside anc reported that glucagon may also be useful in this situatic

Hypotension — Administer vasopressors, e.g., epinep (There is evidence that epinephrine may be the drug of c

Bronchospasm — Administer a $beta_2$-stimulating age theophylline derivative.

For full prescribing information, consult package inser

HOW SUPPLIED: In scored tablets containing 40, 80, o tablet in bottles of 100 and 1000.

Spectrax-SX shown approximately actual size

Medtronic leads the way to man's heart with a remarka new generation of pacemake

Spectrax™...an exceptional new family of pacemakers from Medtronic...provides an abundance of viable alternatives for meeting individual patient needs.

Spectrax-VL...a small, simple, demand pacemaker for longer service life.

Spectrax-SX...the smallest, most versatile programmable pacemaker yet, for precise noninvasive adjustment of rate, pulse width, sensitivity, refractory period, hysteresis, pulse amplitude and pacing modes, can be used as a ventricular or atrial pacemaker.

Both the Spectrax-VL pacemaker and the Spectrax-SX pacemaker have the Medtronic Pacing for Life™ warranty.

The Spectrax family provides for precise management of a wide variety of conditions. This extensive flexibility can make possible a more comfortable, normally active life for many patients.

SPECTRAX™

MEDTRONIC PRODUCT INFORMATION SUMMARY

Medtronic® Implantable Pulse Generators

Intended Uses—Ventricular pacing using an implantable ventricular pulse generator and lead system are for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses). An atrial pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation disorders but with intact, functioning A-V conduction systems.

Contraindications—There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate in patients with normal conduction systems. In certain patients with anomalies of the conduction system (WPW syndrome and related conditions), patients may be benefited or harmed by cardiac pacing. Therefore, electrophysiologic studies are required prior to therapeutic application of pacing. In addition, the patient's age and medical condition may dictate the particular pacing system and implantation procedure used by the physician.

Warnings—Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of unipolar pulse generators or bipolar pulse generators implanted in the unipolar mode because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. (See product labeling for a complete list of warnings and precautions.)

Precautions—The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects—Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

Model 9700/9701 Programmers

Intended Use—The Medtronic® Model 9700 and 9701 Programmers are designed to be used by a physician for noninvasively programming the Medtronic® pulse generators listed in their respective technical manuals. The programmers may also be used to measure the rate and pulse width of implanted pacemakers.

There are no known contraindications or major potential complications associated with use of the programmer. However, these devices should not be used without prior study of the technical manual supplied with each programmer.

Warnings—The programmers should only be used for programming the Medtronic® pulse generators designated in the respective technical manuals. Direct stimulation by energy coupling may occur if the programmers are used on other implanted devices. The programmers are not compatible with pulse generators of other manufacturers. See product labeling for a complete list of warnings and precautions.

Electromagnetic Blood Flowmeters

- Excellent performance in clinical and research applications
- Simple, reliable operation
- Patient protection system
- Zero flow reference
- Convenient readout
- Excellent frequency response
- Low noise — high resolution
- Total system compatibility
- Multiple flow adaptability
- Compact size
- Available with two-channel recorders
- Wide range of blood flow probes available

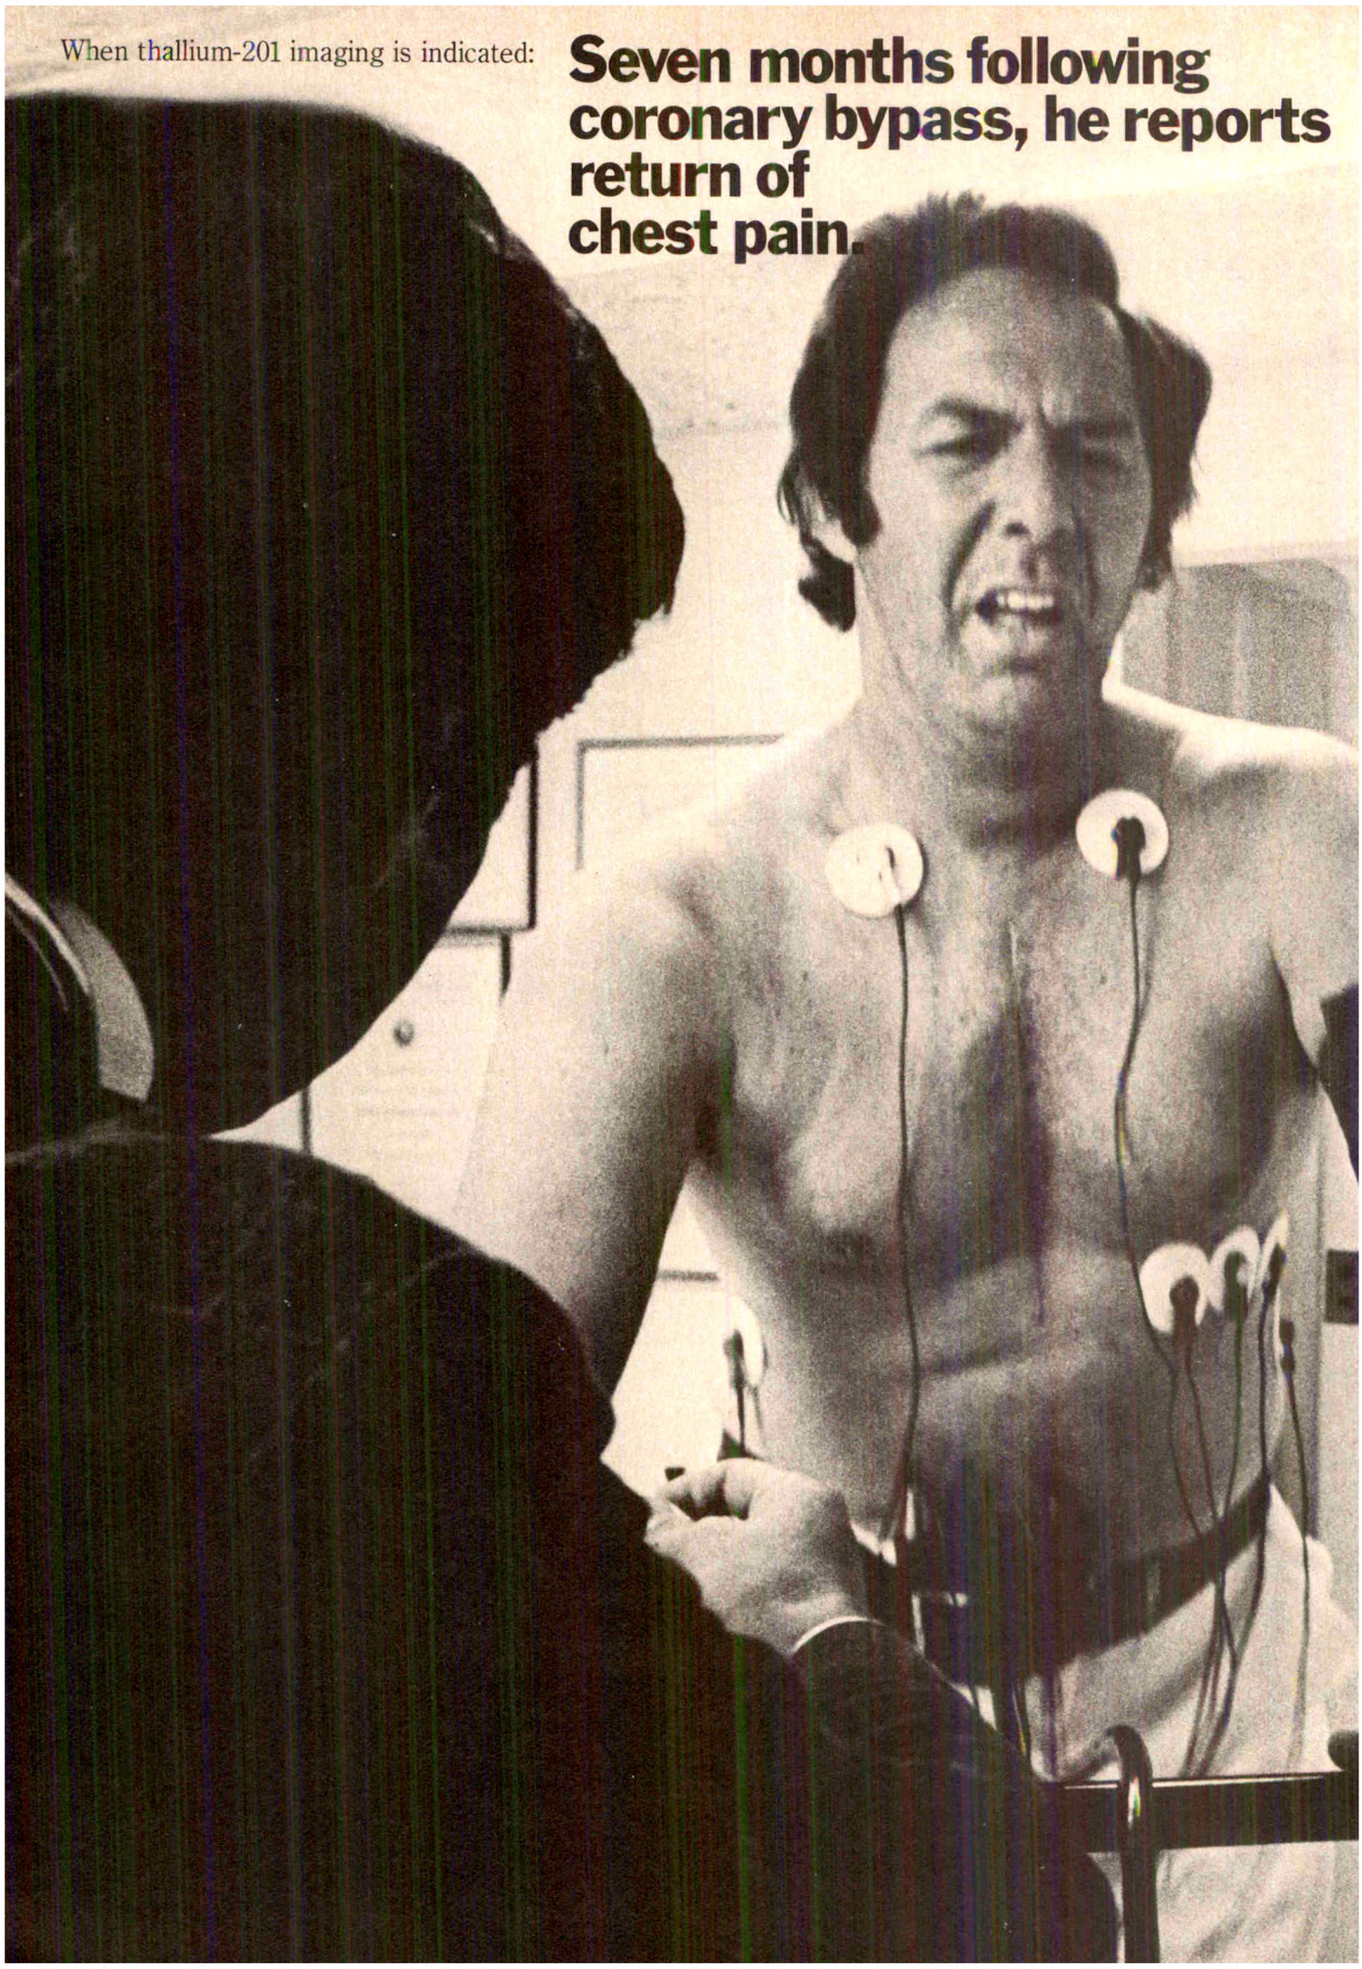
When thallium-201 imaging is indicated:

Seven months following coronary bypass, he reports return of chest pain.



As the population of successful coronary bypass patients continues to grow, physicians will encounter an increasing number who report a return of chest pain after varying postoperative periods.

Complaints of chest pain in post-bypass patients deserve thorough, progressive workup... usually including exercise electrocardiography. Without exercise ECG evidence of myocardial ischemia, the clinician must decide on symptoms alone whether or not to suggest repeat coronary angiography. In such a setting, myocardial perfusion imaging with thallium-201 may rule out—or confirm—the possibility of electrically silent graft occlusion or extension of disease.

Localizes in perfused myocardium

Thallium-201 is a radioactive isotope that, following intravenous injection, distributes within myocardial cells in proportion to regional perfusion. Nuclear medicine imaging performed following injection will display relative regional perfusion and myocardial cell viability.

When used in conjunction with stress electrocardiography, thallium-201 has proven successful in demonstrating regional ischemia that may escape detection by ECG. A region that appears "cold" following exercise and injection, but "fills in" on repeat imaging a few hours later, suggests stress ischemia secondary to fixed stenosis that restricts perfusion during exercise. A region that remains persistently "cold" generally indicates irreversible myocardial scarring.

Reveals graft patency/occlusion

Many institutions routinely perform preoperative and postoperative stress thallium studies to obtain functional evidence of graft-mediated reperfusion of formerly ischemic regions. This sequence of studies can serve as a valuable baseline in the event that the patient returns with a complaint of chest pain:

- If a repeat thallium study discloses ischemia in the regions formerly perfused by the grafts, occlusion may be suspected.
- If the repeat study suggests new areas of ischemia, progression of atherosclerotic disease may have occurred.
- If the repeat study is essentially unchanged from the postoperative findings, nonischemic etiology should be explored.

Useful with/without baseline

Even if baseline stress-thallium studies are not available, this procedure can still provide valuable diagnostic guidance—particularly if it is negative, or displays clear evidence of ischemia in the grafted regions.

Information, teaching program available

New England Nuclear offers an extensive range of journal reprints on the use of thallium-201 imaging, and provides teaching rounds material and reference monographs at no charge, as a service to the profession. For more information on thallium-201, use the coupon below, or call **800-225-1572, ext 2234** toll free.

Thallous Chloride Tl 201

Thallous Chloride Tl 201

For Diagnostic Use

November 1977

Indications and Usage: Thallous Chloride Tl 201 may be useful in myocardial perfusion imaging for the diagnosis and localization of myocardial infarction.

It may also be useful in conjunction with exercise stress testing as an adjunct in the diagnosis of ischemic heart disease (atherosclerotic coronary artery disease).

Contraindications: None known.

Warnings: In studying patients in whom myocardial infarction or ischemia is known or suspected, care should be taken to assure continuous clinical monitoring and treatment in accordance with safe, accepted procedure. Exercise stress testing should be performed only under the supervision of a qualified physician and in a laboratory equipped with appropriate resuscitation and support apparatus.

Ideally, examinations using radiopharmaceutical drug products—especially those elective in nature—of women of childbearing capability should be performed during the first ten days following the onset of menses.

Precautions: Data are not available concerning the effect of marked alterations in blood glucose, insulin, or pH (such as is found in diabetes mellitus) on the quality of thallium Tl 201 scans. Attention is directed to the fact that thallium is a potassium analog, and since the transport of potassium is affected by these factors, the possibility exists that the thallium may likewise be affected.

Thallous Chloride Tl 201, as all radioactive materials, must be handled with care and used with appropriate safety measures to minimize external radiation exposure to clinical personnel. Care should also be taken to minimize radiation exposure to patients in a manner consistent with proper patient management.

No long-term animal studies have been performed to evaluate carcinogenic potential.

Adequate reproduction studies have not been performed in animals to determine whether this drug affects fertility in males or females, has teratogenic potential, or has other adverse effects on the fetus. Thallous Chloride Tl 201 should be used in pregnant women only when clearly needed.

It is not known whether this drug is excreted in human milk. As a general rule nursing should not be undertaken when a patient is administered radioactive material.

Safety and effectiveness in children have not been established.

Adverse Reactions: Adverse reactions related to use of this agent have not been reported to date.

Dosage and Administration: The recommended adult (70kg) dose of Thallous Chloride Tl 201 is 1-1.5mCi. Thallous Chloride Tl 201 is intended for intravenous administration only.

For patients undergoing resting thallium studies, imaging is optimally begun within 10-20 minutes after injection. Several investigators have reported improved myocardial-to-background ratios when patients are injected in the fasting state, in an upright posture, or after briefly ambulating.

Best results with thallium imaging performed in conjunction with exercise stress testing appear to be obtained if the thallium is administered when the patient reaches maximum stress and when the stress is continued for 30 seconds to one minute after injection. Imaging should begin within ten minutes post-injection since target-to-background ratio is optimum by that time. Several investigators have reported significant decreases in the target-to-background ratios of lesions attributable to transient ischemia by two hours after the completion of stress testing.

The patient dose should be measured by a suitable radioactivity calibration system immediately prior to administration.

Radiopharmaceuticals should be used by persons with specific training in the safe use and handling of radionuclides produced by nuclear reactor or particle accelerator and whose experience and training have been approved by the appropriate government agencies authorized to license the use of radionuclides.

How Supplied: Thallous Chloride Tl 201 for intravenous administration is supplied as a sterile, non-pyrogenic solution containing at calibration time, 1mCi/ml of Thallous Tl 201, 9mg/ml sodium chloride, and 9mg/ml of benzyl alcohol. The pH is adjusted to between 4.5-6.5 with hydrochloric acid and/or sodium hydroxide solution. Vials are available in the following quantities of radioactivity: 1.5, 3.0, 4.5, 6.0, and 9.0 millicuries of Thallous Tl 201.

The contents of the vial are radioactive. Adequate shielding and handling precautions must be maintained.

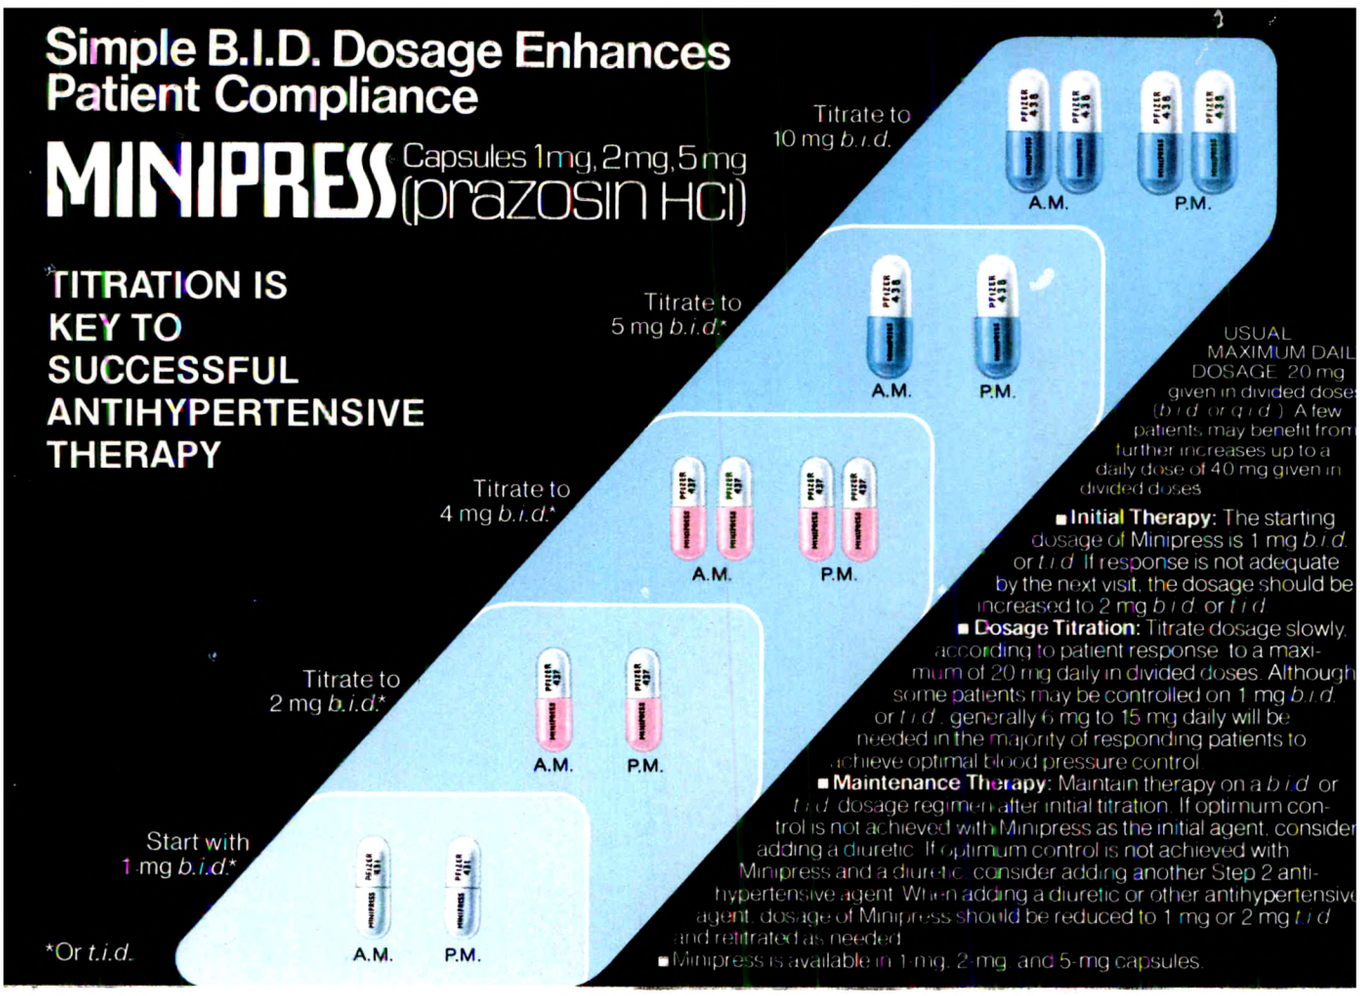
Please see Brief Summary on last page
Before prescribing Minipress, WARNINGS and DOSAGE AND ADMINISTRATION sections should be carefully reviewed.

MINIPRESS® Capsules 1mg, 2mg, 5mg
(prazosin HCl)

Simple B.I.D. Dosage Enhances Patient Compliance

MINIPRESS® Capsules 1mg, 2mg, 5mg (prazosin HCl)

***TITRATION IS KEY TO SUCCESSFUL ANTIHYPERTENSIVE THERAPY**



USUAL MAXIMUM DAILY DOSAGE 20 mg given in divided doses (*b.i.d.* or *q.i.d.*). A few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses.

- **Initial Therapy:** The starting dosage of Minipress is 1 mg *b.i.d.* or *t.i.d.* If response is not adequate by the next visit, the dosage should be increased to 2 mg *b.i.d.* or *t.i.d.*
- **Dosage Titration:** Titrate dosage slowly, according to patient response, to a maximum of 20 mg daily in divided doses. Although some patients may be controlled on 1 mg *b.i.d.* or *t.i.d.*, generally 6 mg to 15 mg daily will be needed in the majority of responding patients to achieve optimal blood pressure control.
- **Maintenance Therapy:** Maintain therapy on a *b.i.d.* or *t.i.d.* dosage regimen after initial titration. If optimum control is not achieved with Minipress as the initial agent, consider adding a diuretic. If optimum control is not achieved with Minipress and a diuretic, consider adding another Step 2 antihypertensive agent. When adding a diuretic or other antihypertensive agent, dosage of Minipress should be reduced to 1 mg or 2 mg *t.i.d.* and retitrated as needed.
- Minipress is available in 1-mg, 2-mg, and 5-mg capsules.

BRIEF SUMMARY

MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*

INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established).

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus.

Genitourinary: urinary frequency, incontinence, impotence.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings).

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

Effect of Verapamil on Regional Coronary and Myocardial Perfusion During Acute Coronary Occlusion

PROTÁSIO L. da LUZ, MD
L. F. MONTEIRO de BARROS, MD
JOÃO JORGE LEITE, MD
FÚLVIO PILEGGI, MD, FACC
LUIZ V. DÉCOURT, MD, FACC

São Paulo, Brazil

To elucidate the mechanism of action of the calcium antagonist verapamil, S-T segment mapping, retrograde coronary flow and regional coronary resistance were studied in 28 dogs subjected to acute coronary occlusion. Retrograde coronary flow was measured directly through catheterization of the distal occluded coronary artery. Regional coronary resistance was calculated by dividing mean distal coronary pressure by coronary flow. Verapamil (0.8 mg/kg) administered intravenously to eight dogs 30 minutes before coronary occlusion significantly reduced S-T segment elevation as compared with occlusion alone ($p < 0.025$); heart rate and diastolic pressure were also reduced ($p < 0.05$) but systolic pressure remained essentially unchanged. When verapamil was given to seven dogs within 30 minutes after coronary occlusion, there was a significant increase in retrograde coronary flow ($p < 0.05$) and a decrease in regional coronary resistance ($p < 0.05$). Simultaneously, heart rate and heart rate-blood pressure product declined significantly ($p < 0.05$), suggesting a reduction in myocardial oxygen consumption. Systolic blood pressure was unaltered, and diastolic pressure decreased only transiently. In 13 control dogs there was no significant change in any of these variables during the observation period. Thus, verapamil during acute coronary occlusion protects the ischemic myocardium by both increasing perfusion and reducing myocardial oxygen consumption.

The new methods to evaluate intensity of myocardial ischemia and infarct size allow identification of hemodynamic factors and therapeutic interventions that can influence the course of an experimental acute myocardial infarction.[1–3] Among such interventions the calcium antagonist verapamil has been the subject of both experimental and clinical studies. Experimentally, verapamil was found to reduce the magnitude of S-T segment elevation in dogs,[4] to decrease selectively regional myocardial contractility in ischemic myocardium[5] and to reduce infarct size as measured with the direct nitroblue-tetrazolium method.[6] In human subjects the drug has primarily been used as an antianginal and an antiarrhythmic agent.[7–9]

Despite these previous investigations, the mechanism of cardiac action of verapamil is not entirely clear. As an antagonist of myocardial calcium influx through slow channels, verapamil decreases myocardial oxygen consumption through reductions in contractility, heart rate and arterial pressure.[10–12] In addition, the drug is a peripheral vasodilator.[12] If such vasodilatory effects also were present in the coronary circulation during acute ischemia, oxygen supply to the ischemic zone could be enhanced.

Thus the drug would have the potential for improving myocardial oxygenation by both reducing oxygen consumption and increasing blood supply. To test this hypothesis, we studied regional myocardial perfusion, and coronary pressure and resistance in open chest dogs subjected to acute coronary ligation.

From the Divisão de Experimentação, Instituto do Coração, Hospital das Clinicas da Universidade de São Paulo, São Paulo, Brazil. Manuscript received May 6, 1979; revised manuscript received August 20, 1979, accepted September 10, 1979.

Address for reprints: Protásio L. da Luz, MD, Avenida Eneas Carvalho de Aguiar, 44 01000, São Paulo, Brazil.

Methods

Experimental preparation: Twenty-eight mongrel dogs of both sexes ranging in weight from 10 to 20 kg were studied. The animals were sedated with morphine sulfate (2 mg/kg intramuscularly) and anesthetized with Nembutal® (30 mg/kg intravenously). Ventilation was controlled with a Takaoka model 670 respirator. The left jugular vein and left carotid artery were cannulated for fluid administration and pressure monitoring. A left thoracotomy was performed through the fifth intercostal space. To expose the anterior surface of the left ventricle, the heart was suspended in a pericardial cradle. Arterial and coronary pressures were measured using a Statham P_{23} Db pressure transducer. Records were obtained on a DR-16 Electronics for Medicine recorder at speeds of 50 mm/s.

Protocol: Two protocols were carried out. In eight dogs (Group I) epicardial S-T segment mapping was performed in the preocclusion period and 15 minutes after ligation of the left anterior descending coronary artery or one of its diagonal branches. This ligation was relieved immediately after the S-T segment mapping. Thirty minutes later verapamil (0.8 mg/kg) was administered intravenously over a 10 to 15 minute period. One hour after the first occlusion, a second coronary ligation was carried out and epicardial S-T mapping was repeated 15 minutes later. Thus, each dog served as its own control. S-T segment elevation was measured 100 ms from the beginning of the QRS complex at 9 to 14 points in each animal; points with S-T elevation greater than 2 mV before occlusion or with conduction disturbances were eliminated.

In 20 dogs (Group II) the left anterior descending coronary artery was dissected approximately 2 cm from its origin and cannulated using a Longdwell catheter (20 gauge, 2.5 inches [6.35 cm] catheter; the artery was ligated immediately proximal to the catheter. Heparin (150 to 250 mg) was given intravenously soon after coronary arterial cannulation; thereafter 25 mg was administered every hour. With use of three-way stopcock system this catheter was connected to a Statham P_{23} Db pressure transducer for an intracoronary pressure recording; additionally a plastic tube was connected to the catheter, thus allowing direct measurement of retrograde coronary flow in a graduated cylinder. Each value is the average of two measurements. To avoid a pressure gradient the tip of the catheter was maintained at the coronary arterial level. An index of regional coronary resistance was calculated by dividing mean intracoronary pressure by retrograde coronary flow.[13]

Control measurements were obtained within 30 minutes after occlusion. Measurements of arterial pressure, heart rate, intracoronary pressure and flow were then obtained every 10 minutes for 90 minutes. Thirteen dogs received no medication and were used as control dogs. In seven dogs, verapamil (0.8 mg/kg) was administered intravenously over an average period of 25 minutes starting soon after control measurements. A drug effect was judged to be present when heart rate decreased by at least 10 beats·min^{-1}. An infusion of saline solution at a rate of 1.0 ml·min^{-1} was maintained intravenously in all dogs for the purpose of volume reposition. In one dog (not included in the statistical analysis) a test coronary occlusion was maintained during 15 minutes; after 45 minutes of recovery a second ligature was performed followed by administration of verapamil; the results were the same as in animals given verapamil after a single ligation.

The data were analyzed using Student's paired t test for changes in variables within the same group and the unpaired t test for comparisons between control and treated dogs.

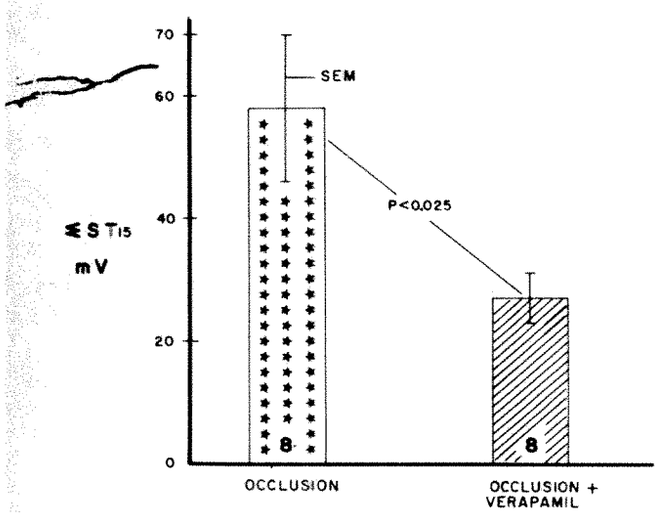

FIGURE 1. Sum of S-T segment elevation (mean values) (ΣST_{15}) during coronary occlusion and occlusion after administration of verapamil. Numbers within the **bars** indicate number of experiments. SEM = standard error of the mean.

Results

Group I: In eight dogs the sum of the S-T segment elevation after 15 minutes of the first coronary occlusion averaged 58.8 ± 11.8 (mean ± standard error of the mean). However, when the occlusion was preceded by administration of verapamil, the sum of S-T segment elevation was only 26.8 ± 10.6 mV; this difference is statistically significant ($p < 0.025$). Figure 1 illustrates the average results. No significant changes in R wave amplitude or new Q waves were observed in either group.

Reduction in S-T segment elevation was associated with significant hemodynamic effects. Thus, a comparison of data during occlusion alone and occlusion preceded by verapamil revealed that heart rate decreased from 166 ± 13.9 to 133 ± 12 beats·min^{-1} ($p < 0.05$), mean arterial pressure decreased from 120 ± 14.6 to 105 ± 10.8 mm Hg ($p < 0.05$) and diastolic pressure from 108 ± 13 to 87 ± 9.5 mm Hg ($p < 0.025$). Systolic pressure also decreased from 137 ± 17.5 to 129 ± 12.6 mm Hg, but the change was not statistically significant.

Group II: The effects of verapamil on regional ischemic myocardium were assessed in seven treated dogs and compared with findings in 13 control dogs. Figure 2 illustrates a typical response to verapamil in a single dog. In control dogs heart rate soon after occlusion was 143 ± 16.8 beats·min^{-1} and it increased by 15 beats·min^{-1} within 10 minutes (difference not significant), remaining essentially unchanged thereafter (Table I). Among treated dogs, initial heart rate was 156 ± 9.1 beats·min^{-1}, a value not significantly different from that in control dogs. During infusion of verapamil heart rate declined by approximately 25 beats·min^{-1} ($p < 0.05$) and remained stable thereafter (Table I).

Initial systolic arterial pressure averaged 104 ± 6.1 mm Hg in control dogs and 107 ± 4.8 mm Hg in treated

APD = arterial diastolic pressure; APS = arterial systolic pressure; C = control period; HR = heart rate.

dogs and did not change significantly in either group. Mean diastolic pressure was 72 ± 5.1 mm Hg in control dogs and also did not change significantly. In treated dogs mean diastolic pressure was slightly higher, averaging 81 ± 4.9 mm Hg, but the difference was not statistically significant. However, a significant reduction in diastolic pressure was noted during verapamil infusion (Table I); the decrease lasted approximately 40 minutes and thereafter diastolic pressure returned to essentially control levels.

These systemic effects were associated with marked changes in regional ischemic myocardium. Initially there were no significant differences between control values of retrograde coronary flow and regional coronary resistance between the control group and the treated dogs (Table II). In control dogs initial retrograde flow averaged 1.1 ± 0.2 ml·min^{-1} and remained essentially unchanged during 50 minutes but decreased slightly in the following 40 minutes of observation, although this change was not statistically significant (Fig. 3). Coronary resistance showed variable trends; 50 minutes after control measurements, coronary resistance increased in five dogs, was reduced in one and remained unchanged in four. At the end of observation the average value had increased but the change did not reach statistical significance (Fig. 4).

Initial retrograde coronary flow among treated dogs was also 1.0 ± 0.2 ml·min^{-1}. However it increased consistently and significantly ($p < 0.05$) after administration of verapamil (Fig. 3). At the same time, regional coronary resistance decreased significantly during and after administration of verapamil (Fig. 4).

To elucidate further the effect of verapamil on myocardial oxygen supply/demand ratio, heart rate-

systolic arterial blood pressure product, an index of myocardial oxygen consumption,[14] was plotted against regional retrograde coronary flow in (Fig. 5). The drug augmented regional perfusion while reducing oxygen demand.

Discussion

Our results show that verapamil decreases the magnitude of ischemic injury after acute coronary occlusion, reduces regional coronary resistance and increases coronary blood flow to the ischemic zone; these changes occurred while myocardial oxygen consumption was reduced as indicated by the heart rate-arterial blood pressure product.

Possible limitations of study: The validity of our results regarding regional myocardial resistance and flow largely depends on the validity of the methods used. Regional coronary flow measurements were made

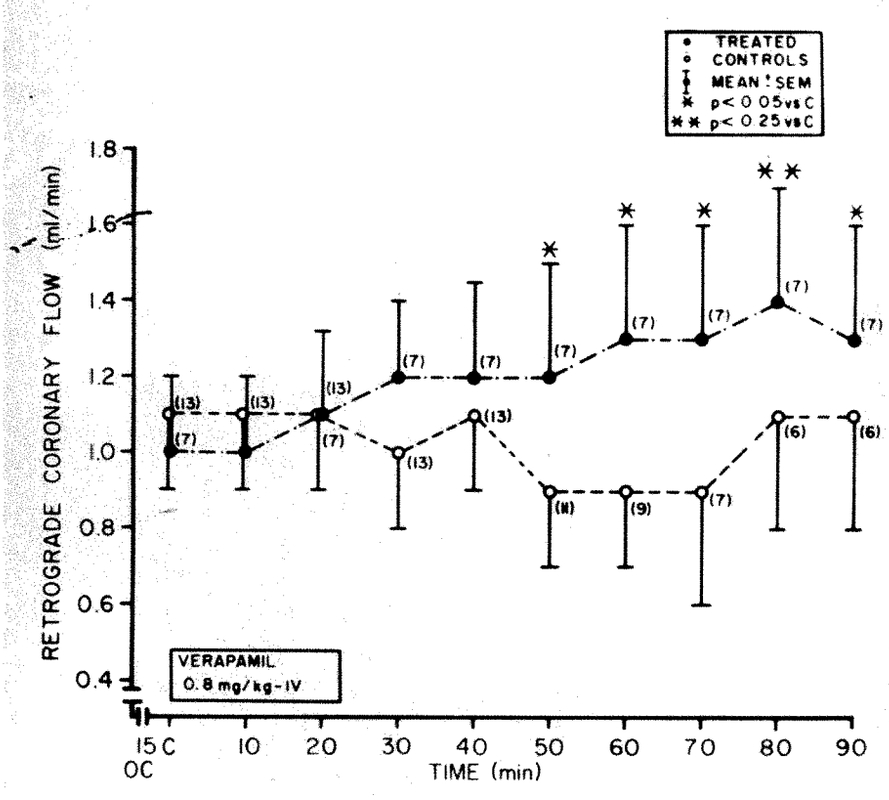

FIGURE 3. Increases in perfusion of the ischemic myocardium induced by verapamil. Retrograde coronary flow was measured by direct drainage into a graduate cylinder. Values are expressed as mean values ± standard error of the mean (SEM). Numbers in parentheses indicate number of animals studied at each point. C = control; OC = occlusion.

directly in a graduated cylinder, using a small scale syringe to minimize the observer's error. The position of the catheter within the coronary artery and the position of the draining tube tip in relation to the coronary arterial level was carefully watched to avoid technical error; heparin was given to preclude local thrombosis. Even with these precautions such direct measurements may be imprecise. Furthermore, our measurements were made with the catheter open to atmospheric pressure, which reduces resistance to flow only to that created by the draining tubular system, whereas in the intact coronary bed resistance is probably different. In addition, directly measured backflow has been found to be less than the collateral flow estimated with rubidium-86[15,16]; thus, we cannot state the actual value of regional perfusion. Nevertheless, because control and treated dogs were studied rigorously in the same manner comparisons are valid with respect to directional changes.

Calculation of an index of regional coronary resistance also has limitations. First, measured coronary pressure probably reflects not only pressure in the ischemic zone, but also transmitted pressure from

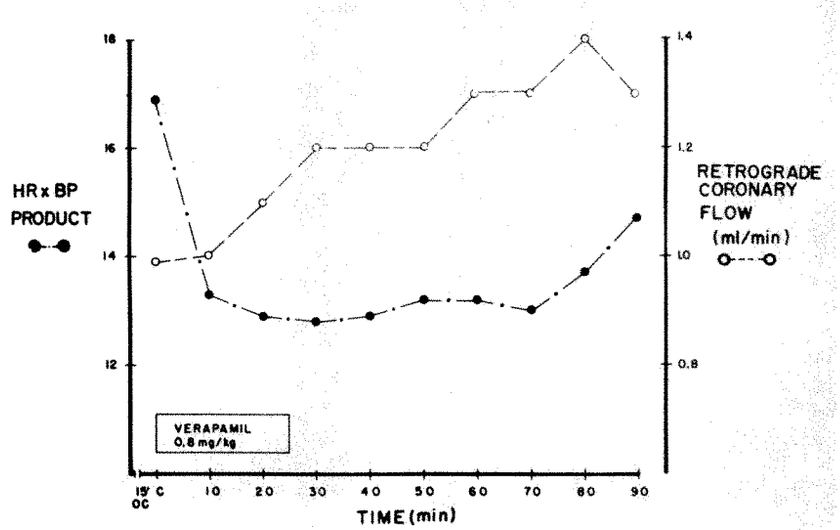

FIGURE 5. Relation between perfusion of the ischemic myocardium, as indicated by the retrograde coronary flow, and myocardial oxygen consumption, as indicated by the product of heart rate (HR) and blood pressure (BP) in control dogs and dogs treated with verapamil subjected to acute coronary occlusion. Verapamil increased perfusion while reducing oxygen consumption. Values are expressed as mean values ± standard error of the mean.

nonischemic adjacent areas through collateral channels. However, because verapamil may act on these channels, calculation of coronary resistance affords useful information. Second, as previously mentioned, this calculation includes flow values that are not precisely those of the intact coronary circulation. Finally, pressure and flow recordings were not strictly simultaneous, but because they were obtained within a few beats of each other this time factor is practically irrelevant. As for flow, resistance cannot be taken as an absolute value, but rather as an index that reflects changes in the regional coronary tone.

Previous studies on effects of verapamil on acute ischemia: Verapamil diminished S-T segment elevation and the magnitude of ischemia when given 30 minutes before coronary occlusion. This effect occurred in all dogs and the magnitude of S-T segment elevation after administration of verapamil was only half of that during occlusion alone, suggesting that the protective effect of verapamil is of biologic significance. Previous experimental studies identified a beneficial effect of verapamil during acute myocardial ischemia. Thus, Smith et al.[4] also found reduction in S-T segment elevation when the drug was given 15 minutes after coronary occlusion. Reimer et al.,[6] who gave verapamil before coronary occlusion in dogs, documented reduction in the magnitude of necrosis assessed by the nitroblue tetrazolium method. Nayler et al.[17] observed that verapamil protects the isolated rabbit heart against some effects of hypoxia; thus verapamil reduced the myocardial cell increase in sodium and loss of potassium, the rate of creatine kinase release and the depletion of adenosine triphosphate and creatine phosphate stores, and it greatly diminished mitochondrial swelling and vacuolization as well as membrane disruption in hearts subjected to severe hypoxia.

However, Karlsberg et al.,[18] who injected verapamil 5 hours after the initial increase in plasma creatine kinase after coronary occlusion in dogs, failed to observe the protective effect of the drug; in their study, verapamil increased flow to the normal myocardium but not to the ischemic zone. The discordance between our data and those of other investigators with the data of Karlsberg et al. may be explained by the timing of drug administration. It takes at least 2 hours for creatine kinase to increase in plasma after coronary occlusion[2]; yet in the study of Karlsberg et al. the drug was actually administered 7 hours after induction of ischemia. It has been shown that drugs such as hyaluronidase,[19] methylprednisolone[20] and propranolol[21] progressively lose their protective effect on the ischemic myocardium as the interval from coronary occlusion to administration increases; beyond 4 to 6 hours after occlusion significant protection has not been documented, a finding that underscores the crucial importance of the time factor in determining the ultimate impact of one intervention on infarct size. Hence, it is possible that the lack of effect observed by Karlsberg et al. was due to late drug administration. In patients with unstable angina at rest, Parodi et al.[22] recently demonstrated a significant decrease in frequency of ischemic attacks when orally administrated verapamil was used rather than a placebo. Overall, our data and those of other studies[4,6,17,22,23] support the conclusion that under selected conditions, verapamil protects the myocardium against the effects of ischemia and hypoxia.

Mechanism of verapamil's action: In previous investigations[7–11] the mechanism of action of verapamil has mainly been attributed to its inhibitory effects on calcium transport, and consequently to its negative inotropic effects. In our study no direct measurements of the inotropic state were performed. Nevertheless, a decrease in heart rate and heart rate-systolic blood pressure product was observed, indicating a reduction in myocardial oxygen consumption. These changes could account in part for the reduction in the magnitude of ischemia indicated by the reduction in S-T segment elevation. The most significant finding in our study is that verapamil lowered regional coronary resistance and allowed an increase in perfusion of the ischemic zone. An increase in flow occurred despite a transient reduction in diastolic blood pressure and a persistent decrease in heart rate. Thus, increases in retrograde flow cannot be attributed to higher perfusion pressure or increased myocardial oxygen consumption and a local vasodilatory effect must be assured.

Because ischemia is in itself a potent vasodilatory stimulus,[24] a reduction in local coronary resistance may indicate either that verapamil has an additional effect that produces further dilatation of the ischemic vessels or that ischemia is not uniform and fewer ischemic vessels can respond to verapamil, whereas those already maximally dilated will not be affected by the drug. Our data do not allow distinction between these two possibilities. On the basis of previously known effects of ischemia,[24] we can only hypothesize that the effect of this drug occurred primarily on collateral channels. These channels are numerous in dogs and could perfectly provide augmentation of flow.

The biologic significance of such an increase in retrograde coronary flow in our study is not clearly established. Because coronary flow distribution between endocardial and epicardial zones was not assessed, we cannot exclude the possibility that local flow "shunting" occurred in such a way that more ischemic endocardial zones were not benefited by overall augmentation in regional perfusion. However, the decrease in S-T segment elevation indicates a reduction in the ischemic process.[25] Because S-T segment elevation 15 minutes after coronary ligation has been found to correlate closely with creatine kinase depletion 24 hours after occlusion,[25] it seems reasonable to assume that the ischemic process was halted by verapamil. Nevertheless, more direct measurements of flow distribution are needed before a definitive statement on this matter can be made.

Finally, the simultaneous reduction in blood pressure-heart rate product and augmentation in retrograde coronary flow indicates that the mechanism of action of verapamil during acute coronary occlusion is twofold: On the one hand, the drug reduces myocardial oxygen demand and on the other it increases regional

perfusion, possibly through a local coronary vasodilatory effect. Although reduction in oxygen consumption is attributed classically to calcium blockade and consequent negative inotropic effect,[7-11] the increased perfusion to the ischemic myocardium is an additional mechanism of action of verapamil. This dual effect on oxygen supply/demand ratio, in addition to the previously known antiarrhythmic effects of verapamil,[26,27] makes this agent of particular interest for protection of the acutely ischemic myocardium.

Clinical implications: Our results cannot be extrapolated directly to human beings for reasons beyond obvious differences in species. First, the coronary circulation of dogs is probably normal and collateral vessels are abundant, whereas in human beings with acute myocardial infarction, usually more than one vessel is involved in the atheromatous process and collateral channels are less developed. The response of diseased vessels to a vasodilating agent may be quite different from that of normal vessels. Second, this study was performed in anesthetized dogs and there is evidence that anesthesia can influence the response of coronary vessels to drugs.[28] Nevertheless, the possibility that verapamil may reduce oxygen demand and improve oxygen supply in patients with acute myocardial infarction is raised by our results. Because of the potential importance of reduction of infarct size as a means of decreasing mortality and left ventricular dysfunction during acute coronary occlusion, a clinical trial seems well justified.

Altered Coronary Flow Responses to Vasoactive Drugs in the Presence of Coronary Arterial Stenosis in the Dog

WILLIAM P. SANTAMORE, PhD
PAUL WALINSKY, MD

Philadelphia, Pennsylvania

Recent in vitro observations of human coronary arteries have suggested that intraluminal pressure can be a determinant of the resistance to flow through the stenosis. This study examined whether similar pressure-dependent changes in stenotic resistance could be observed and analyzed in an open chest, anesthetized, animal model of coronary arterial stenosis. Without stenosis, intracoronary isoproterenol (1 μg) or nitroglycerin (10 μg) increased flow and decreased coronary resistance, whereas methoxamine (500 μg) or vasopressin (0.2 U) decreased flow and increased coronary resistance. After partial arterial constriction, administration of isoproterenol (1 μg) resulted in a decrease in coronary pressure from 61.2 $\pm$ 2.5 to 39.4 $\pm$ 2.7 mm Hg ($p \leq 0.05$), a 23 percent decrease in distal coronary resistance ($p \leq 0.05$) and a 22 percent decrease in flow associated with an increase in stenotic resistance of 2.34 $\pm$ 0.97 ($p \leq 0.05$). Similarly, nitroglycerin caused a decrease in coronary pressure from 55.7 $\pm$ 3.1 to 42.1 $\pm$ 3.6 mm Hg ($p \leq 0.05$), a 29 percent increase in distal coronary resistance and only a 1 percent increase in flow associated with a 38 percent increase in stenotic resistance. Methoxamine caused an increase in coronary pressure from 62.8 $\pm$ 2.0 to 73.6 $\pm$ 3.4 mm Hg ($p \leq 0.05$), an 18 percent increase in distal coronary resistance, an 8 percent decrease in flow and a 10 percent decrease in stenotic resistance. Vasopressin caused an increase in coronary pressure from 61.0 $\pm$ 1.5 to 99.2 $\pm$ 7.1 mm Hg ($p \leq 0.05$), a 239 percent increase in distal coronary resistance but only a 45 percent decrease in flow associated with a decrease in stenotic resistance of 1.33 $\pm$ 0.91 ($p \leq 0.05$).

Passive changes in the stenotic area caused by coronary pressure changes are postulated as part of the mechanism for the observed changes in stenotic resistance. This hypothesis is strengthened by the changes in stenotic resistance and radiographic analysis obtained from an in vitro carotid arterial preparation. The pressure-dependency of stenotic resistance could be an additional factor in the treatment of patients with coronary artery disease.

Coronary arterial stenosis has a complex influence on blood flow through and beyond the narrowed segment. Factors that have been recognized as determining resistance across a stenosis include the absolute radius, the relative percent of narrowing, the length of the stenosis and the viscosity and velocity of fluid flowing through the stenosis.[1-4] A recent in vitro study suggested that stenotic resistance was also dependent on intraluminal pressure.[5] In that study proximal coronary arteries, obtained from fresh postmortem adult hearts, were examined under various flow rates, perfusion pressures and distal resistances. In coronary arteries with eccentric lesions (a plaque on one side not completely surrounding the lumen), the resistance to flow was found to be dependent on the perfusion pressure: lowering the perfusion pressure increased the resistance, whereas increasing the perfusion pressure decreased the re-

sistance. This study suggested that interventions that lower the distal coronary arterial pressure could increase the hemodynamic resistance of the stenotic segment of the artery, whereas interventions that raise the distal coronary pressure could decrease the hemodynamic resistance of the stenotic segment of the artery.

Recently, Schwartz et al.[6] and Walinsky et al.[7] in our laboratory documented an alteration of the normal response to momentary coronary arterial occlusion in the presence of partial coronary arterial constriction. We observed a dependence of stenotic resistance on distal coronary pressure, a finding similar to the in vitro observations on human coronary arteries described previously. It was the objective of this study to expand our initial observations by examining the coronary response to a variety of vasoactive drugs in a canine model of high grade coronary stenosis and to determine the mechanism for the observed changes in stenotic resistance by using an in vitro arterial preparation.

Methods

Initial Preparation

Animal studies were performed in 10 mongrel dogs weighing 29.5 to 34.1 kg. All animals were pretreated with morphine (1 mg/kg), anesthetized with alpha-chloralose (100 mg/kg) and mechanically ventilated. Supplemental doses of alpha-chloralose were given as needed. Arterial blood partial pressures of oxygen (P_{O_2}) and carbon dioxide (P_{CO_2}) and pH were periodically monitored throughout the experiment by a blood gas analyzer (Instrumentation Laboratory). Respiratory adjustments or intravenous infusions of sodium bicarbonate, or both, were made when necessary to keep blood gases and pH within a physiologic range of pH 7.32 to 7.42, P_{CO_2} 32 to 42 mm Hg, P_{O_2} above 70 mm Hg.[8] The heart was exposed through a left lateral thoracotomy and suspended in a pericardial cradle. A catheter was advanced in retrograde fashion from the right femoral artery and positioned in the ascending aorta to measure aortic pressure. Depending on the coronary arterial anatomy, an electromagnetic flow probe (Biotronex Laboratory, Inc.) was placed around either the left anterior descending artery or the circumflex artery. If the left anterior descending artery was utilized, the site of isolation varied from the proximal to the mid portion of the artery. If the circumflex artery was utilized, the site of isolation was always proximal to the first major marginal branch.

A variable snare type of occluder was placed distal to the flow probe. The snare consisted of a 1 mm wide band of Teflon® passed around the artery, through stiff tubing, and attached to a machinist's micrometer. The micrometer and tubing were mounted above the dog in a position that prevented traction from being exerted on the stenosis during the cardiac cycle both before and after drug interventions. The snare could be closed by small precise amounts according to a 0.01 mm micrometer scale. The advantage of a narrow (1 mm) snare occluder was that a higher degree of stenosis could be obtained before resting coronary blood flow was affected.[1] Distal to the micrometer-adjusted snare occluder, 1–0 nylon suture was placed around the coronary artery. The ends of the suture were inserted through a piece of polyethylene tubing, 3 cm in length. Zero flow was obtained by pulling the ends of the suture while pressing on the polyethylene tubing against the coronary vessel. Thus, zero flow could be obtained without changing the setting on the micrometer-adjusted snare occluder. Distal to the occluder, a 22 gauge catheter was inserted either into a diagonal branch or directly into the circumflex artery. The catheter was used for monitoring distal coronary arterial pressure and for all intracoronary injections. In the region perfused by the artery in which instruments were placed a small platinum electrode was inserted into the myocardium to record an intramyocardial electrogram.

Aortic pressure, coronary blood flow, coronary pressure distal to the snare and an intramyocardial electrogram were recorded on an Electronics for Medicine physiologic recorder (model DR8). Mean pressures were obtained electronically. Distal coronary resistance was calculated by dividing mean distal coronary arterial pressure by mean coronary blood flow. Stenotic resistance was calculated by dividing the mean pressure gradient across the stenosis by mean coronary flow.[1,9] The mean pressure gradient across the stenosis was calculated as the mean aortic blood pressure minus mean coronary arterial pressure.

At the end of each experiment the electromagnetic flow probe was calibrated by timed collection of blood. The coronary artery distal to the site of insertion of the 22 gauge catheter was occluded. The coronary blood then flowed through the proximal coronary artery and the coronary catheter into a graduated cylinder.

Statistical analysis was performed by using the Wilcoxon sign rank test[10] to compare the control values with the values obtained after injection of the pharmacologic agent.

Experimental Procedure: Vasoactive Drugs

After the initial preparation, the effects of intracoronary injection of isoproterenol (1 μg) and methoxamine (500 μg), each diluted in 1 ml of physiologic saline solution, were examined before and after partial constriction of the coronary artery in six dogs. All injections were made through the catheter used to monitor distal coronary pressure. Before constriction of the coronary artery, isoproterenol (1 μg) was rapidly injected into that artery while all physiologic variables were recorded continuously for a 10 minute period before and after the injection. Next, methoxamine (500 μg) was injected into the coronary artery while the physiologic variables were recorded. Mean distal coronary pressure was then gradually reduced to 60 mm Hg by tightening the snare occluder. Mean distal coronary pressure was reduced to 60 mm Hg because 60 mm Hg has been shown to be close to the limits of autoregulation[11] and ventricular mechanical integrity.[12] All physiologic variables were recorded for at least 15 minutes with the mean coronary pressure at 60 mm Hg to yerify stability. Isoproterenol (1 μg) and methoxamine (500 μg) were again administered into the coronary artery by the technique outlined earlier. To avoid any interaction between the drugs, there was a 20 minute period between intracoronary injections. Further, the order in which the drugs were given was alternated. In half the experiments isoproterenol was injected first and in the other half, methoxamine was injected first.

In six dogs, after the initial preparation, the effects of intracoronary injections of nitroglycerin (10 μg) and vasopressin (0.2 U), each diluted in 1 ml physiologic saline solution, were examined before and after partial coronary arterial constriction by the methods outlined earlier. Again, to avoid drug interaction, there was at least a 20 minute period between intracoronary injections and the order in which the drugs were given was alternated.

In Vitro Carotid Arterial Preparations

To test further the dependency of stenotic resistance on intraluminal pressure, an in vitro arterial preparation was used. The in vitro carotid arterial preparation was used to exclude alpha and beta adrenergic stimulation, reflexes, sys-

temic blood pressure changes, pulsatile blood flow and pressure, collateral vessels and platelet plugging as potential causes of the stenotic resistance changes. The carotid artery was used because of its easy removal from the dog and its long length without branches. In each study, the artery was frozen, thawed, suspended in air and kept moist by externally applied saline solution. By design, therefore, only the passive characteristics of arterial stenosis were studied by means of this preparation. In 11 mongrel dogs (11.3 to 40.8 kg) the left and right common carotid arteries were rapidly removed immediately after the anesthetized animal was killed. The arteries were frozen in physiologic saline solution until they were studied.

Two types of experimental protocols were performed: constant flow and constant pressure. For the constant flow experiments, the artery was attached between points a and b (Fig. 1) and stretched to its original in vivo length. The artery was kept moist by externally applied physiologic saline solution. A Harvard syringe pump maintained a constant flow rate (22.9 ml/min between a pressure range of 0 to 400 mm Hg) of an isotonic dextran solution (1.7 centipoise). With use of a circumferential snare (previously described), various stenotic resistances between 0.5 and 6.0 mm Hg/ml·min^{-1} were established, with a high peripheral resistance (20 gauge Longdwel needle). Stenotic resistance was calculated as the pressure gradient across the stenosis (P1 − P2) divided by the flow.[7,8] Distal resistance was calculated as distal pressure divided by flow. With the initial stenotic resistance set and the pressures recorded, the distal resistance was halved three times by sequentially opening stopcocks S1, S2 and S3. At each level of distal resistance, the pressures were recorded. Stopcock S1 was then closed, reestablishing the initial conditions. If stenotic resistance varied more than 5 percent from the control value, the data were discarded. This procedure was repeated 10 times with different initial stenotic resistances for each artery studied in this experimental group. The pressures were recorded on an Electronics for Medicine physiologic recorder. The pressure transducers were carefully calibrated to insure equal sensitivity by simultaneously exposing the pressure transducers to the reservoir pressure. Without flow, both transducers recorded the same pressure level. The absolute pressure value was determined by measuring the height of the fluid column above the pressure transducers.

For the constant pressure experiments, the artery was attached between points a and b (Fig. 1), stretched to its original length and kept moist by externally applied physiologic saline solution. The reservoir consisted of a 4 liter bottle filled with physiologic saline solution and suspended at a fixed height above the artery. Using a circumferential snare, stenotic resistances between 0.5 and 6.0 mm Hg/ml·min^{-1} were established with a high peripheral resistance (20 gauge Longdwel needle). With the initial stenotic resistance set, the pressures and flow were recorded. The flow was determined by a 1 minute collection in a graduated cylinder. The peripheral resistance was halved three times by sequentially opening stopcocks S1, S2, S3. At each level of peripheral resistance, the pressures and flow were recorded. Stopcock S1 was then closed, reestablishing the initial conditions. If the calculated stenotic resistance varied more than 5 percent from the control value, the data were discarded. This procedure was repeated 10 times for each artery.

Radiographic Analysis

Radiographic techniques were used to investigate the stenotic geometric changes that occurred with changes in peripheral resistance. In five dogs, immediately after sacrifice the left or right common carotid artery was rapidly removed and attached to the constant flow–external constrictor apparatus (Fig. 1). The Dextran solution was replaced with contrast material (Angio-conray®). The circumferential snare was used to establish stenotic resistances between 1.0 and 6.0 mm Hg/ml·min^{-1}. A radiogram was taken (40 kV, 100 mA, 8 seconds, Kodak gray tone imaging film) and the proximal and distal pressures were recorded. The stopcocks S1, S2 and S3 were then simultaneously opened, lowering the peripheral resistance to approximately one eighth of its initial value. A second radiogram was taken and the pressures recorded. This procedure was repeated only four times for each artery thereby limiting the total experimental time to less than 15 minutes.

High resolution radiograms were obtained by using microangiographic techniques.[13] This involved the use of high resolution film without an image intensifier (Kodak gray tone

imaging film, 2,000 line pairs per inch); the use of Angioconray with its high iodine content (800 mg/ml sodium iothalamate); placing the artery close to the film; using fresh arteries; and limiting the experimental time. The radiograms were analyzed by using a dissecting microscope with a calibrated eye piece (magnification ×20). Four observers measured the proximal, stenotic and distal diameters of each vessel, before and after the peripheral resistance was lowered. The mean and standard error of the mean were calculated for each diameter measurement. The percent of stenosis was based on the reduction in cross-sectional area[9] and was calculated as: percent of stenosis = $100\ (1 - D_s^2/D_p^2)$, where D_s is the stenotic diameter and D_p is the proximal diameter.

Results

Vasoactive Drugs

Methoxamine: Figure 2 (top) shows the typical response to intracoronary methoxamine (500 μg) before coronary arterial constriction. After administration of methoxamine, coronary flow decreased, whereas distal coronary resistance increased. Figure 2 (bottom) shows for the same experiment the response to methoxamine after partial coronary occlusion. Methoxamine then caused a slight increase in coronary flow, an increase in coronary pressure, an initial increase in distal coronary resistance and a decrease in stenotic resistance.

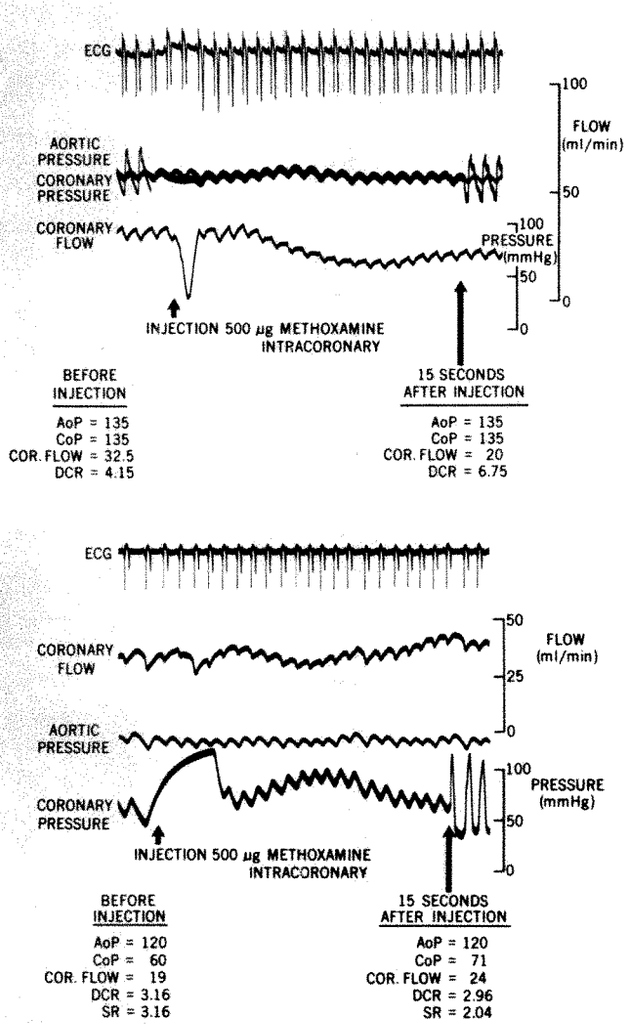

FIGURE 2. The response in one experiment to intracoronary administration of methoxamine (500 μg) before (**top**) and after (**bottom**) partial coronary arterial constriction. AoP = mean aortic pressure; CoP = mean coronary pressure; Cor. Flow = mean coronary blood flow; DCR = distal coronary resistance; ECG = electrocardiogram; and SR = stenotic resistance.

Table I summarizes the effects of intracoronary methoxamine before and after partial coronary occlusion in six dogs. Before occlusion, methoxamine led to a large increase in distal coronary resistance and a decrease in coronary flow. After partial coronary arterial occlusion, methoxamine caused an insignificant decrease in coronary flow. By 15 seconds, coronary flow had decreased from 27.4 ± 4.6 to 25.3 ± 3.6 ml/min. This decrease in coronary flow was significantly less than the decrease in coronary flow that occurred before coronary arterial constriction ($p \leq 0.05$). This altered coronary flow response was associated with a coronary pressure increase and a slight, insignificant decrease in stenotic resistance.

Vasopressin: Table II summarizes the effects of vasopressin (0.2 U) in six experiments. Before coronary arterial constriction, vasopressin caused a large increase in distal coronary resistance and a decrease in coronary flow. After partial coronary arterial constriction, vaso-

pressin still caused an increase in distal coronary resistance and a decrease in coronary flow. Coronary pressure increased while stenotic resistance decreased. These studies illustrate that when constriction of distal coronary vasculature is severe, the reduction in stenotic resistance is insufficient to alter effectively the decrease in coronary flow.

Isoproterenol: The typical response to intracoronary isoproterenol (1 μg) given before coronary arterial constriction is shown in Figure 3 (top). After the isoproterenol injection, there was a large increase in coronary flow subsequent to the decrease in distal coronary resistance. Heart rate also increased. After partial coronary arterial constriction, there was a strikingly different response to isoproterenol (Fig. 3, bottom). Coronary flow and coronary presssure now decreased and stenotic resistance and heart rate increased. The decrease in coronary flow was associated with a large increase in stenotic resistance.

Table III summarizes for six experiments the effects of isoproterenol before and after partial coronary arterial constriction. Before such constriction, isoproterenol resulted in a significant decrease in distal coronary resistance and an increase in coronary flow. Heart rate increased 31 beats/min ($p \leq 0.05$). After partial coronary arterial constriction, isoproterenol resulted in a decrease in coronary flow that was significantly ($p \leq 0.05$) different from the normal coronary flow response to isoproterenol. This altered coronary flow response was associated with a large increase in stenotic resistance and a decrease in distal coronary pressure. Heart rate increased 49 beats/min ($p \leq 0.05$).

Nitroglycerin: Table IV summarizes the data from the six nitroglycerin experiments. Before coronary arterial constriction, nitroglycerin led to a transient increase in coronary flow and a decrease in distal coronary resistance. After partial coronary arterial constriction, nitroglycerin caused a decrease in distal coronary resistance and distal coronary pressure, and an increase in stenotic resistance. Although distal coronary resistance decreased, coronary blood flow was unaltered. This coronary flow response was significantly different from the normal coronary flow response to nitroglycerin ($p \leq 0.05$) and was associated with a large increase in stenotic resistance and a decrease in distal coronary pressure.

Stenotic resistance versus distal coronary pressure: Figure 4, combining the data on stenotic resistance and distal coronary pressure in the four experimental groups, shows the changes in stenotic resistance that occurred after administration of a vasoactive drug versus the distal coronary pressure. For all the data shown in Figure 4, the initial value of coronary pressure (abscissa) before the vasoactive drug was between 56

and 64 mm Hg and the initial value of stenotic resistance (ordinate) was between 0.5 and 5.6 mm Hg/ml·min^{-1}. As coronary pressure decreased after vasodilation, stenotic resistance increased ($p \leq 0.01$); and, as coronary pressure increased above 60 mm Hg after vasoconstriction, stenotic resistance decreased ($p \leq 0.01$).

In Vitro Arterial Preparation

Constant flow experiments: Table V is based on 86 observations in nine arteries. Stenotic resistance *always* increased as the distal resistance or distal pressure (P2) decreased; the greater the decrease in distal resistance, the greater the corresponding increase in stenotic resistance. Further demonstrating the dependency of stenotic resistance on intraluminal pressure is the observation that the stenotic resistance changes were bidirectional. Lowering the distal pressure increased the stenotic resistance, whereas increasing the distal pressure decreased the stenotic resistance. At the end of each observation, the peripheral resistance was increased from 0.7 to 4.9 mm Hg/ml·min^{-1}; this caused the stenotic resistance to decrease and return to its control value.

Constant pressure experiments: Table VI is based on 31 observations in five arteries. The mean perfusion pressure was 112.4 ± 0.2 mm Hg. On the basis of the

flow response, the data were divided into two groups. In Group A, the flow always increased as the distal resistance decreased. In Group B, the flow initially increased as the distal resistance was decreased. With subsequent lowering of the distal resistance, flow decreased. The decrease in flow was due to the large increase in stenotic resistance. The initial stenotic resistance was significantly higher ($p \leq 0.05$) and the distal pressure significantly lower ($p \leq 0.05$) in Group B than in Group A. Thus, the data indicate that a severe stenosis (Group B) was required for flow to decrease as the distal resistance was decreased.

Radiographic Analysis

The radiographic analysis demonstrated that lowering the peripheral resistance caused a significant decrease in stenotic diameter and a significant increase in percent stenosis. Figure 5 shows a typical radiogram obtained from one experiment. Figure 6 summarizes the results of the radiographic analysis. Lowering the peripheral resistance caused a significant reduction in the stenotic and distal diameters and a significant increase in percent of stenosis. These changes were associated with an increase in stenotic resistance from 2.48 ± 0.53 to 5.23 ± 0.74 mm Hg/ml·min^{-1} ($p \leq 0.01$). If the stenotic resistance is assumed to be inversely proportional to the diameter to the fourth power, then decreasing the diameter from 0.59 to 0.50 mm would cause an approximate doubling of the stenotic resistance, which is similar to the observed experimental results. Thus, this group of experiments verifies that the changes in stenotic resistance were partially due to changes in stenotic area caused by the reduction of intraluminal pressure.

Discussion

Coronary flow response to vasoactive drugs: Methoxamine and vasopressin, before coronary arterial constriction, increased distal coronary arterial resistance and decreased coronary flow, a response similar to that reported by others.[14–16] After partial coronary arterial occlusion, both methoxamine and vasopressin still increased distal coronary resistance. In the methoxamine experiments, the decrease in stenotic resistance either attenuated the decrease in coronary flow or caused an increase in coronary flow. However, in the vasopressin experiments the decrease in stenotic resistance was insufficient to overcome the large increase in distal coronary resistance, and coronary flow always decreased.

Before partial coronary arterial occlusion, intracoronary administration of isoproterenol or nitroglycerin increased coronary blood flow and decreased coronary resistance. This response is similar to the results of other investigators.[17–21] After partial coronary arterial occlusion, intracoronary isoproterenol or nitroglycerin still decreased distal coronary resistance. However, the coronary flow response was attenuated (or even reversed in some experiments) by the large increase in stenotic resistance.

Thus, in the presence of severe stenosis, the normal coronary flow response to vasoactive drugs can be attenuated or even reversed. The mechanism for this phenomenon appears to be an interaction between the stenosis and the distal coronary vasculature. Methoxamine and vasopressin, which constricted the distal

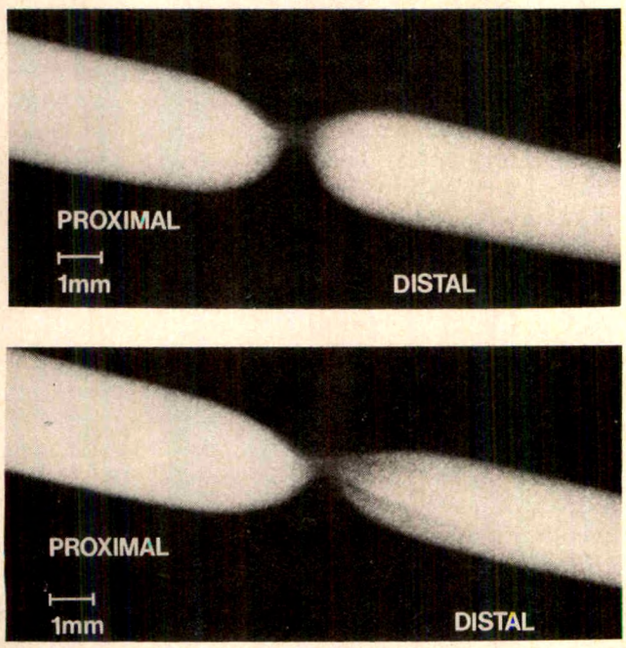

FIGURE 5. Typical radiogram obtained before (**top**) and after (**bottom**) the peripheral resistance was lowered.

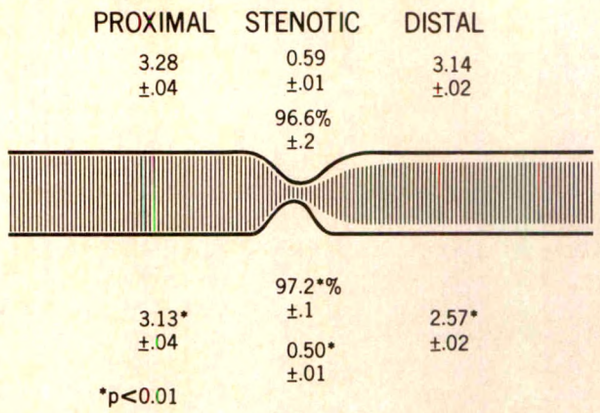

FIGURE 6. Sketch of artery before (**solid line**) and after (**vertical bars**) the peripheral resistance was lowered. Data on bottom are the same values obtained after the peripheral resistance was lowered.

coronary vasculature, also reduced the hemodynamic severity of the stenosis. Because total coronary resistance is the sum of stenotic resistance and distal coronary resistance, if the decrease in stenotic resistance was greater than the increase in distal coronary resistance, then total coronary resistance decreased. This decrease in stenotic resistance altered or even reversed the normal increase in total coronary resistance and decrease in coronary blood flow after the injection of the vasoconstrictors. Conversely, isoproterenol and nitroglycerin, which dilated the distal coronary vasculature, increased the hemodynamic severity of the stenosis. This increase in stenotic resistance altered or even reversed the normal decrease in total coronary resistance and increase in coronary blood flow after the injection of the vasodilators. Thus, the results of this study would indicate that in the presence of severe stenosis, the interaction between the stenosis and distal coronary vasculature will ultimately determine whether a vasoactive agent will increase or decrease coronary blood flow.

Stenotic resistance changes induced by changing distal resistance or pressure: Similarly, in the in vitro, carotid arterial preparation, changes in stenotic resistance were also induced by changing the distal resistance or pressure. Increasing the distal resistance or pressure always decreased the stenotic resistance. Conversely, lowering the distal resistance or pressure always increased the stenotic resistance. In the constant pressure experiments, distal resistance was not always associated with a flow increase. With higher initial values for stenotic resistance, flow actually decreased as the distal resistance decreased. This occurred because of the large increase in stenotic resistance.

Changes in stenotic resistance versus changes in luminal area: Radiographic analysis demonstrated that the changes in stenotic resistance were due at least in part to changes in luminal area. Lowering the distal pressure or resistance decreased the luminal area. With the snare, an external force is applied to the vessel that is opposed by the intraluminal pressure. Decreasing the intraluminal pressure would tend to collapse the vessel, whereas increasing the intraluminal pressure would tend to expand it.[22] With severe stenosis, only minimal changes in stenotic area will drastically affect flow.[1,3] Thus, in the presence of severe stenosis, these minimal changes in luminal area could cause part of the observed increase in stenotic resistance.

An increase in turbulence in blood flowing through the stenosis could also explain part of the increase in stenotic resistance.[9] However, changes in blood flow turbulence probably occurred secondary to luminal area changes. Lowering the distal pressure decreased the luminal area. If flow remained constant (as in the in vitro constant flow experiments), the flow velocity through the stenosis would increase, leading to increased blood flow turbulence.

Several potential mechanisms for the observed changes in stenotic resistance were unsubstantiated by our findings. Platelet plugging has been shown over long periods of time to influence flow through a stenosis.[23] However, the rapid response observed after administration of vasoactive drugs, the decrease in stenotic resistance after vasoconstrictors and the increase in stenotic resistance after isoproterenol and nitroglycerin preclude platelet plugging as a mechanism for the responses observed in this study.[24] Systemic arterial pressure was unchanged. Finally, any potential changes in collateral blood supply would occur in the distal

coronary vasculature and therefore could not account for the observed changes in stenotic resistance.

Previous studies on stenotic resistance changes: Several in vivo studies have demonstrated changes in stenotic resistance that were postulated to be caused by changes in geometry of the stenosis. Kreuzer and Schenk[25] demonstrated an increase in stenotic resistance in the iliac artery caused by distal vasodilation. They believed that vasodilation altered the degree of stenosis by increasing the unstenosed cross-sectional luminal area. Previously[7] we demonstrated an increase in stenotic resistance caused by momentary coronary arterial occlusion. Schwartz et al.[6] observed similar changes in stenotic resistance and postulated that the increase in stenotic resistance was due to a passive decrease in the stenotic area secondary to the reduction in intraluminal pressure. In unsedated dogs in which instruments are chronically in place, Gould[26] observed dynamic increases in the hemodynamic severity of coronary arterial stenosis after coronary vasodilation. The increase in stenotic resistance after coronary vasodilation was probably due to the dilation of the epicardial artery adjacent to the stenosis, which caused more severe relative percent narrowing and a larger divergence angle. However, Lipscomb and Hooten,[27] using stenotic models, found that the pressure gradient across the coronary stenosis was not affected by varying the exit angle of the stenosis from 10 to 90°. More studies appear necessary to determine the exact mechanism or mechanisms involved in the increase in stenotic resistance after a reduction in the distal pressure.[6,7,25,26]

Obviously, experimental arterial stenosis is only a model or imitation of human arterial stenosis. However, a recent in vitro study suggested that in man stenotic resistance is also dependent on intraluminal pressure.[5] In that study proximal coronary arteries obtained from fresh postmortem human hearts were examined at various flow rates and levels of perfusion pressure and distal resistance. In coronary arteries with eccentric lesions (a plaque on one side not completely surrounding the lumen), the resistance to flow was found to be dependent on the perfusion pressure. At lower perfusion pressures the resistance increased, whereas at higher perfusion pressures the resistance decreased. These results are similar to ours.

Clinical implications of this study: In the presence of severe stenosis distal coronary vasodilation might paradoxically decrease blood flow by increasing the hemodynamic severity of the stenosed arterial segment. In light of Logan's observations,[5] this phenomenon would probably occur only in patients with eccentric lesions. Patients with hard, fixed concentric lesions would probably not exhibit this characteristic. Further, this study indicates that vasodilation can cause a severe reduction in distal coronary pressure. The reduction in coronary pressure could lead to a maldistribution of myocardial blood flow and therefore the reduction in coronary pressure may be a factor in the production of subendocardial ischemia. This study also implies a very important role for collateral vessels: Such vessels not only would help to maintain myocardial blood flow, but also would help to maintain distal coronary pressure and to stabilize the hemodynamic status of the stenosed arterial segment. Obviously, the foregoing arguments are speculative and additional studies are required to relate these experimental results to the clinical situation. Conceivably, however, the interaction between stenosis and the distal coronary vasculature after administration of vasoactive drugs could be an additional factor in the therapy of patients with coronary arterial disease.

SPECIAL COMMENTARY

Dynamic Coronary Stenosis

K. LANCE GOULD, MD, FACC

Seattle, Washington

Recognition of coronary vasospastic disease, of the effects of long or multiple stenoses and of the enormous variability of clinical estimates of severity of stenosis has increased sophistication in interpreting coronary arteriograms during recent years. However, the field of coronary arteriography remains curiously retarded from a scientific point of view, without answers to profound clinical questions such as, How severe must a stenosis be before it alters ventricular function or myocardial metabolism? What severity of stenosis can be detected noninvasively? What is the progression or regression of severity of stenosis with, for example, antilipid or antiplatelet drugs? Such practical problems hinge on the definition of severity or changes in severity and therefore raise more basic scientific questions. These include: How should stenoses be quantified physiologically and hydraulically? What effect does large vessel vasomotion and distal arteriolar resistance have on proximal lesions, and how can dynamic changes in stenoses be systematically and quantitatively accounted for? The report by Santamore and Walinsky[1] in the current issue of this Journal documents the effects of vasoactive drugs on the severity of experimental coronary stenoses. The study is important because it brings into sharp focus several fundamental issues on the nature of arterial stenoses and on assessment of their severity. This commentary therefore briefly reviews the published data on the dynamic changes of "fixed" arterial stenoses, outlines the basic concepts of fluid dynamics underlying quantitative geometric analysis of stenoses and poses some essential questions that are unresolved.

The Experimental Observations

Shipley and Gregg[2] in 1944 first showed that peripheral resistance of an arterial bed influenced the calculated resistance of an upstream large arterial stenosis. Kreuzer and Schenk[3] in 1973 described an increase in stenosis resistance during distal vasodilation of the dog hind limb and hypothesized that vasodilation of the normal artery on either side of the stenotic segment caused more severe percent stenosis with corresponding greater stenosis resistance. Gould et al.[4] in 1975 reported that coronary stenosis resistance as conventionally calculated increased as coronary flow increased and that distal pressure decreased after administration of coronary vasodilators in open chest dogs. Logan[5] in the same year demonstrated in postmortem perfused human hearts that stenosis resistance increased during a decrease in distal coronary pressure. Swartz et al. in abstract form[6] in 1977 and in a full report[7] in 1979 demonstrated that with a critically severe coronary stenosis in open chest dogs, coronary flow decreased with a large increase in stenosis resistance and reduction in distal coronary pressure after the vasodilatory stimulus of contrast medium or 10 seconds of occlusion. Walinsky et al.[8] in 1979 independently reported similar findings. Gould[9] described in intact chronically instrumented animals a proportionately greater pressure loss and therefore greater severity of stenosis during high flows after administration of coronary vasodilators as compared with severity of stenosis at resting flow levels. Anderson et al.[10] recently found in intact instrumented dogs a close dependence of renal arterial stenosis resistance on distal pressure and renal vascular bed resistance. All of these studies using external cuff constrictors of normal arteries in experimental animals showed increasing stenosis severity after distal vasodilation associated with a reduction in distal arterial pressure.

In contrast to findings in animal studies, Brown et al.[11] and Doerner et al.[12] using quantitative coronary arteriography in clinical studies reported a significant decrease in severity of stenosis after administration of nitroglycerin or nitroprusside. Who is right in this apparent conflict of results? Do "fixed" stenoses change and, if so, for the worse or for the better and under what conditions?

Interpretation of Experimental Observations

There are solid data indicating that experimental coronary stenoses become functionally more severe with vasodilation of the distal coronary bed and perhaps less severe with vasoconstriction. Previous workers[5–8] as well as Santamore and Walinsky[1] have proposed that the

reduction in distal or intraluminal coronary pressure known to occur after administration of coronary vasodilators, either with or without an increase in coronary flow, causes a mechanical collapse of the wall of the stenotic segment of coronary artery. This hypothesized mechanism is a reasonable possibility in normal dogs with externally compressed flexible coronary arteries or in eccentric lesions of human coronary arteries in which part of the wall of the stenotic segment remains flexible and able to collapse with a decrease in intraluminal pressure.

However, there are problems with this explanation. Brown[11] and Doerner[12] and their colleagues described consistent increases in cross-sectional area of coronary stenosis after administration of coronary vasodilators in man and a corresponding marked decrease in stenosis resistance derived from stenosis geometry. A partial explanation for these conflicting results is that in the animal studies the vasodilatory stimulus affected primarily the distal arteriolar coronary bed leading to a reduction in intraluminal pressure, whereas in the clinical studies the vasodilatory stimulus (nitroglycerin) affected primarily the epicardial large coronary arteries. Thus, distal coronary arteriolar vasodilators may make stenoses worse and distal arteriolar vasoconstrictors may make them better, as suggested by the study of Santamore and Walinsky.[1] Proximal arterial large vessel dilators may make stenoses better, as Brown and Doerner and co-workers have suggested, or conceivably worse, depending on how they are analyzed, as discussed subsequently. Even so, the problem is more complicated. A thorough explanation requires a bit of simple mathematics, a subject usually eliciting a glazing of the eyes and deep yawns. To counter this impending response, let me say a modest conceptual error has been propagated in the published reports and will be perpetuated unless terminated by an enlighted readership.

Defining severity of stenosis resistance: In the reports mentioned earlier,[2–4] the increased calculated stenosis resistance found with increasing flow (or decreased distal coronary bed resistance), although derived from experimental observations of pressure and flow, is an experimental artifact due to the way stenosis resistance is calculated from mean pressure and mean coronary flows; this increased stenosis resistance does not imply more severe geometric severity. The artifact arises from the definition of stenosis resistance as follows: $R_s = G/Q$, where R_s is stenosis resistance, G is the mean reduction in pressure or gradient across the constriction, and Q is mean flow through it. The experimental relation between the mean coronary stenosis pressure gradient and mean coronary flow during life is linear with the regression line intercepting the flow axis at zero gradient, indicating that at some positive mean flow values there is no measurable mean pressure gradient.[4] This relation can therefore be expressed as the equation $G = a + b\,Q$, where a is the flow or X axis intercept at zero gradient and b is the slope of the regression line relating the pressure gradient, G, to the flow, Q, that is, the change in gradient per unit change in flow, $\Delta G/\Delta Q$. Substitution of this equation for G in the previous equation for calculated stenosis resistance gives the final expression $R_s = G/Q = b + a/Q = \Delta G/\Delta Q + a/Q$. This equation shows that stenosis resistance calculated from mean pressure and mean flow values is a hyperbolic function of flow. As flow increases from low values, R_s increases in a nonlinear fashion and is not a fixed constant at all flows because of the last term of the equation, a/Q. This observation has been confirmed experimentally, with stenosis resistance increasing in nonlinear fashion as flow increased from low or resting values.[4] Thus, by definition stenosis resistance calculated from mean values of pressure and flow is dependent on flow despite constant, fixed stenosis geometry and is therefore an unsatisfactory measure of severity of stenosis.

Physiologically, the pressure losses across a stenosis are proportionately less during systole than during diastole and the gradient-flow relation during systole is different (less severe) from that during diastole; therefore, mean pressure-flow recordings are "distorted" by the myocardial compressive effects of systole and do not reflect the true diastolic hydraulic characteristics of the stenosis.[9] Therefore, mean pressure gradient is not acceptable as a descriptor of hydraulic severity of coronary stenoses. Utilization of high fidelity phasic recordings of pressure and flow avoids this particular distortion artifact because the diastolic pressure gradient-flow relation is curvilinear and passes through the origin without a flow or X axis intercept.[9] However, because the diastolic gradient-flow relation is curvilinear, stenosis resistance calculated from phasic data as gradient/flow is also flow-dependent and has limited value in defining severity of stenosis over a wide range of flows. More complex methods of analysis are therefore required using high fidelity phasic data as discussed subsequently.

Previous reports[6–8] and the current study of Santamore and Walinsky[1] describe this expected increase in calculated stenosis resistance with increased coronary flow without explicitly acknowledging this experimental artifact. However, in addition, these studies include a more important observation, namely, that in the presence of a relatively severe stenosis coronary flow decreased after distal coronary vasodilation. Because the flow decreased rather than increased, the mathematic artifact of increasing calculated stenosis resistance with increasing coronary flow does not apply. In other reports[5,9] severity of stenosis was determined by fitting diastolic or nonsystolic experimental data to equations derived from classic fluid dynamics not affected by the calculated resistance artifact. Both of these studies also showed a real increase in hydraulic severity of coronary stenoses at high flows after administration of coronary vasodilators. Thus, there is unequivocal evidence that experimental coronary stenoses become hydraulically worse after distal bed vasodilation.

The results of Brown[1] and Doerner[12] and their coworkers conflict with those of the current study of Santamore and Walinsky.[1] In the latter study the stenosis diameter of the in vitro model decreased after an

eight-fold decrease in distal intraluminal distending pressure. Such gross changes in distal pressure are not frequently observed in vivo after administration of vasodilators, and the measured change in stenosis diameter averaged only 0.09 mm (from 0.59 to 0.50 mm). If such small changes can in fact be reliably measured, it is not clear that this degree of geometric change could account quantitatively for the large increase in stenosis resistance and decrease in coronary flow in the in vivo part of the current study. The question of altered stenosis resistance thus evolves to a problem of defining severity in quantitative geometric terms. This subject requires a brief review of the principles of fluid dynamics.

Principles of Fluid Dynamics

According to accepted laws of fluid dynamics applied to laminar steady flow in an in vitro system of rigid tubes, the energy or pressure loss due to constriction of a tube is caused primarily by (1) viscous friction between layers of fluid in the stenotic segment according to the Hagen-Poisuelle Law, and (2) flow separation or vortex formation (eddying or swirling) at the downstream end of the stenosis.[13–17] The pressure loss, ΔP, is related to the flow velocity, V, through a stenotic tube according to a general equation that may be written in simplified form as $\Delta P = FV + SV^2$. F is the coefficient of pressure loss due to viscous friction and is dependent on relative percent narrowing, absolute diameter, and length of the stenosis. S is the coefficient of pressure loss due to flow separation and is dependent on relative percent stenosis and exit or divergence angle of the stenosis. V is the first power of instantaneous, mean cross-sectional flow velocity, and V^2 is the second power of velocity. An additional term may be added to account for inertial losses associated with pulsatile flow. However, the inertial effects are small for stenoses of greater than 50 percent diameter narrowing[17] and can be omitted in relation to the coronary circulation. *The fluid dynamic equations can be written as follows in terms of coronary flow velocity (1) or volume flow (2):*

$$\Delta P = \frac{8\pi\mu L}{A_s}\frac{A_n}{A_s}V + \frac{\rho k}{2}\left(\frac{A_n}{A_s} - 1\right)^2 V^2 \qquad (1)$$

$$\Delta P = \frac{8\pi\mu L}{A_s}\frac{1}{A_s}Q + \frac{\rho k}{2}\left(\frac{1}{A_s} - \frac{1}{A_n}\right)^2 Q^2, \qquad (2)$$

where ΔP is pressure loss across the stenosis, μ is absolute blood viscosity, L is stenosis length, A_n is the cross-sectional area of the normal artery, A_s is the cross-sectional area of the stenotic segment, V is flow velocity, ρ is blood density, k is a constant related to the exit or divergence angle, Q is volume flow. Blood viscosity and density are constant, and the relation between pressure loss and coronary flow or flow velocity is therefore a function of stenosis geometry.

In the flow equation (2), $1/A_n$ is much smaller than $1/A_s$ for stenoses of modest to severe degree. Therefore, A_n, or the normal size of the artery for modest or severe narrowing, has little influence on severity of stenosis in the flow equation. For similar reasons, changes in the normal arterial diameter due to vasomotion have negligible effects in the flow equation. The effects of stenosis in the flow equation are dependent primarily on the absolute diameter of the stenotic segment, not on relative percent stenosis or diameter of the normal adjacent artery, although the latter has some minimal influence. Severity of stenosis in the velocity equation (1) is highly dependent on relative stenosis as well as on absolute stenosis diameter and would therefore be sensitive to vasomotion of the normal part of the artery.

With use of quantitative coronary arteriographic analysis, the general form of these equations has been proved to apply to intact awake chronically instrumented animals, but the quantitative accuracy of these equations for predicting in vivo pressure gradients has not yet been demonstrated.[9] Experimental data in models suggest that the details of stenosis geometry such as eccentricity, streamlining or exit angle divergence and entrance shape are not of great importance.[18,19] In simple terms, both equations show that the pressure gradient across a stenosis increases sharply and in a progressive curvilinear fashion with increases in coronary flow. Therefore, the effects of a stenosis will be least during coronary flow at rest and greatest at high levels of coronary flow.

Should Percent Stenosis or Absolute Stenosis Dimensions Be Used to Assess Severity?

This question is really the same as asking should the velocity equation or the flow equation be used? The advantages of using the flow equation are that (1) the equation is simpler, (2) it deals with volume flow, which physicians intuitively understand better than velocity, and (3) a single measure of absolute stenosis diameter and length defines the stenosis relatively independent of how big the normal artery is on either side of the stenosis; thus, there would be little change in effective severity of stenosis with vasodilation of the normal arterial segment as long as the stenotic segment remained fixed. The disadvantage of the flow equation is that it does not provide a quantitative assessment of stenosis independent of knowledge of blood flow in the stenotic artery, a limitation that in some comparative situations makes the flow equation appear erroneous from an intuitive, common sense point of view. For example, in absolute terms, a 2 mm diameter narrowing in a coronary artery with a diameter of 4 mm is a 50 percent stenosis, which we know to be of mild physiologic significance. However, a 2 mm stenosis in an aorta with a normal diameter of 20 mm causes a 90 percent stenosis, which we know is a severe physiologic lesion. However, the geometric severity of the 2 mm narrowing according to the flow equation would be comparable in the two instances. We could interpret the significance of that geometric severity only if we knew it were a coronary artery or the aorta; in other words, only if we knew how much flow would normally be going through the artery. Thus, use of the flow equation is of little value unless we also know the normal volume of flow in the artery. Using a modified flow equation and volume flow measurements, Lipscomb and Hooten[18] demonstrated exactly

this point, that is, the size of the vessel on either side of the stenosis, and therefore percent stenosis, has no effect on the severity of the gradient-flow relation *if volume flow is measured.* If flow velocity is measured, the change in normal vessel caliber on either side of the stenosis would have a profound effect on the gradient-velocity relation used to describe severity of stenosis.

The velocity equation does not have this problem because it includes a measure of the normal arterial size and because, in the arteries of the body, mean cross-sectional flow velocities tend to be fairly uniform within a relatively narrow range in arteries of different sizes (between 20 and 40 cm/s at rest and four times that at peak); by comparison, volume flow at rest ranges from very small values in small arteries to 6,000 cc/min or greater in the aorta at rest). This stenosis geometry defined by the velocity equation provides a better assessment of severity without requiring knowledge of which specific artery is involved or how much flow goes through it. This logic also explains why percent stenosis has served for so many years as an empiric clinical measure of severity even though the precise reason for its validity is not widely recognized. The disadvantages of the velocity equation are that it is more complicated, flow velocity is less intuitively understood and stenosis severity will change dynamically with adjacent arterial vasomotion.

Thus, the choice of measuring either arterial volume flow or arterial flow velocity for any in vivo or in vitro experiment predetermines, by definition, whether absolute stenosis diameter or relative percent narrowing is the dominant factor in describing functional severity of stenosis. Failure to recognize this fact has led to apparently conflicting data. All studies in which the gradient-volume flow relation was used to describe stenosis severity conclude that absolute stenosis diameter is the most critical dimension. All studies in which the gradient-velocity relation was used to describe stenosis severity conclude that relative percent stenosis is the most critical dimension. No study to date acknowledges that the experimental data and those corresponding conclusions are obligatory, depending on the variables measured—flow or velocity. A corollary to this observation having direct clinical relevance follows: To ask the question what percent stenosis affects flow is to ask an illogical question that cannot be rigorously answered. The proper questions would be either (1) What is the absolute stenosis diameter that affects the normal volume flow in a specific artery (that is, coronary, iliac or other artery) where the normal volume flow in the artery would have to be known, or (2) What is the percent narrowing and absolute stenosis in any nonspecified artery that reduces its flow velocity?

Gradient-velocity versus gradient-flow relation: I believe that the velocity equation is more general, more broadly applicable to all arteries categorically and therefore probably more useful for scientific purposes. This issue is so important to arteriography and concepts of stenosis, both scientifically and clinically, that a graphic illustration is necessary. Figure 1, upper panel, shows the hypothetical gradient-velocity relation (that is, a graphic plot of the velocity equation) for stenoses of equal physiologic severity in a large and a small artery. Physiologic severity in this example is defined as the capacity to increase flow four times over resting values with a maximal pressure gradient of 25 mm Hg. The curve for the small artery is the same as that for the large artery, indicating equal hydraulic severity. The lower panel of Figure 1 shows the gradient-velocity relation for stenoses of unequal physiologic severity but of equal absolute stenosis diameter, 1.5 mm. The more severe physiologic lesion is associated with a capacity to increase flow by only 0.5, or 50 percent, with a 50 mm Hg maximal gradient; it has a steeper gradient-velocity curve than that of the milder physiologic lesion, regardless of arterial size. Thus, by using velocity measurements (or equations), physiologically equal lesions in arteries of different sizes appear hydraulically equal and physiologically unequal lesions appear hydraulically unequal.

The opposite is true of volume flow measurements and equations. Figure 2, upper panel, shows the hypo-

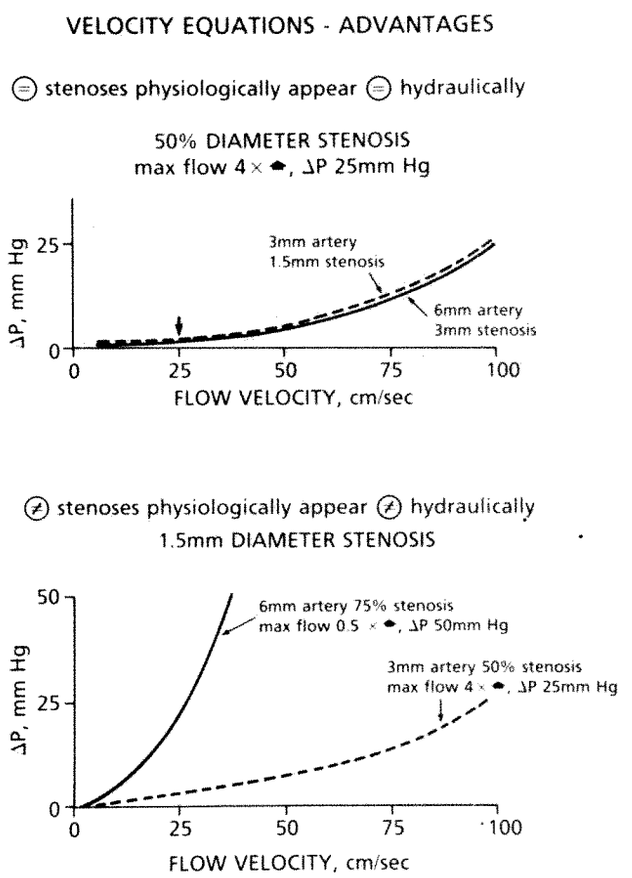

FIGURE 1. Upper panel, relation of pressure gradient (ΔP) and arterial flow velocity in the normal unstenosed part of the artery for physiologically equal stenoses (50 percent diameter) in a small artery with a diameter of 3 mm (**dashed line**) and in a large artery with a diameter of 6 mm (**solid line**). The **arrow** indicates the normal value[9] for coronary flow velocity at rest (25 cm/s). **Lower panel,** similar relation for physiologically unequal stenoses of 1.5 mm absolute diameter in the small (**dashed line**) and the large (**solid line**) artery.

thetical gradient-flow relation for stenoses of equal physiologic severity (as defined previously) in a small and a large artery. The curve for the small artery is steeper and leftward, indicating less flow for the same gradient; by this plot the small artery appears to have a hydraulically more severe lesion than the larger artery when, in fact, the two stenoses are physiologically the same. Thus, stenoses of equal physiologic severity in two arteries of different sizes appear unequal hydraulically if analyzed in terms of volume flow equations. The lower panel of Figure 2 shows the gradient-flow relation for stenoses of unequal physiologic severity but of equal absolute stenosis diameter, 1.5 mm as before. The more severe physiologic lesion, which is associated with a capacity to increase flow by only 0.5 or 50 percent with a 50 mm Hg maximal gradient, has a gradient-flow curve that is the same as for a physiologically milder lesion in the smaller artery. Thus, physiologically unequal lesions in two different arteries appear hydraulically equal if analyzed in terms of volume flow equations. For these reasons, I favor the use of velocity equations and velocity measurements in experimental studies and conclude that relative percent stenosis is more important

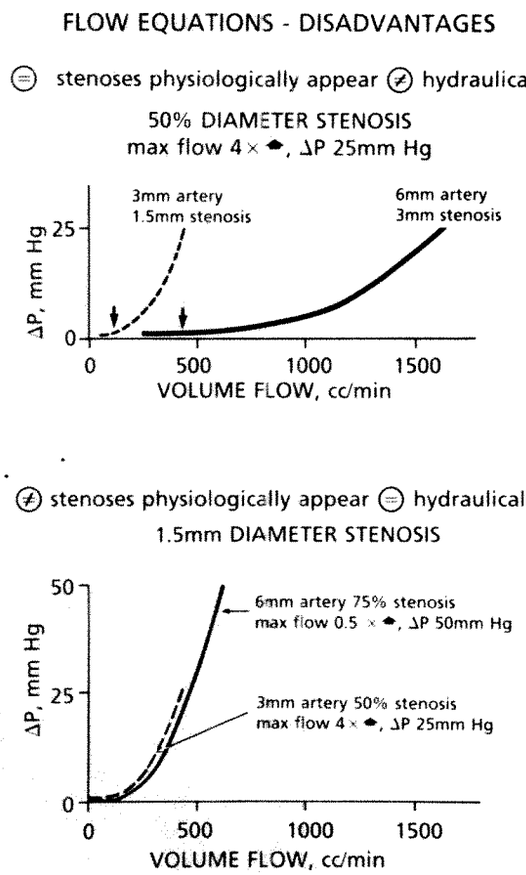

FIGURE 2. Upper panel, relation of pressure gradient (ΔP) and arterial volume flow for physiologically equal stenoses in a small (**dashed line**) and a large (**solid line**) artery. The **arrows** represent normal volume flow at rest in each of these two arteries, corresponding to a flow velocity at rest of 25 cm/s. **Lower panel,** similar relation for physiologically unequal stenoses of 1.5 mm absolute diameter in the small (**dashed line**) and large (**solid line**) artery.

than absolute stenosis diameter although the latter plays some role, especially if it is long.

Comparison of stenosis before and after an intervention: These examples suggest that velocity equations and correspondingly relative percent stenosis are most useful for assessing severity of stenoses in general or for comparing lesions in arteries of different sizes. However, there is one situation in which flow equations and measurement of absolute stenosis diameter may be quite useful, namely, when comparing the geometric severity of a stenosis before an intervention, such as administration of nitroglycerin, to the *same stenosis in the same artery* after the intervention. Inherent in such comparisons before and after an intervention is the underlying question: Do coronary volume flow and pressure to the distal coronary bed improve or deteriorate with the intervention? The unknown that normally limits the interpretability of the flow equations and absolute stenosis diameter is the need to know the volume flow that normally passes through the artery. This unknown becomes irrelevant when comparing the effects of interventions on the same stenosis in the same artery. Vasodilation purely of the normal segment of an artery on either side of a fixed stenosis will alter the velocity-gradient relation making the stenosis hydraulically worse in correct fluid dynamic terms; that is, for a given flow velocity the pressure gradient is greater. In this particular circumstance, the previous experimental question does not concern the exact physical description or measurement of the stenosis itself but rather of the effects on volume flow and perfusion pressure—in a sense, distal physiologic effects. To answer a question about effects of a stenosis on volume flow obviously requires use of the flow equation and a graph of the volume flow-gradient relation as a measure of stenosis severity. In this instance flow velocity, V, would decrease in proportion to the increase in cross-sectional area of the normal artery, A_n, adjacent to the stenosis; therefore, volume flow, or $A_n \times V$, and pressure to the distal myocardial bed would not change. Thus, the use of flow equations in the studies of Brown[11] and Doerner[12] and colleagues is an appropriate and proper application because they examined changes in stenosis after an intervention in comparison with the same stenosis under control conditions. Their experimental question asked whether the volume flow-gradient relation determined with quantitative coronary arteriography became worse or better after administration of nitroglycerin or nitroprusside.

Standard for assessing stenosis severity: In several years of searching for a "gold standard" for analyzing severity of stenosis, I have found no simple answer applicable to all situations. The most reasonable general rules are: *Rule 1,* for assessing severity of stenosis in broadly applicable free-standing absolute terms for nonspecified arteries in general, for comparing different stenoses in different arteries or for averaging measures of severity of stenosis in different experiments or patients, the best exact measure of severity of stenosis is the determination of the friction coefficient, F, and the separation coefficient, S, in the equation $\Delta P = FV + SV^2$. These coefficients can be obtained by two methods.

The first requires instrumented experimental animals in which phasic diastolic, beat by beat gradient across the stenosis and flow velocity are measured (with an implanted periarterial Doppler flowmeter); F and S are then determined by using a computer to find the quadratic equation, $\Delta P = FV + SV^2$, best fitting the experimentally recorded ΔP, V data as previously described.[9] The other way can be carried out in patients or experimental animals by taking high quality orthogonal coronary arteriograms and calculating F and S from X-ray geometry as shown in the velocity equation. All coefficients to be compared or compiled into means must be obtained either at rest or at maximal vasodilation or over a range of flows by a rest-vasodilation composite equation.[9] Comparing one stenosis at rest with another during maximal vasodilation is incorrect. The closest, nonexact approximation of this rule is to measure relative percent stenosis.

Rule 2, for comparing a stenosis to itself before and after an intervention in order to determine whether the intervention increased volume blood flow to the distal coronary bed, the flow equation and a graph of the volume flow-gradient relation are the most useful. The analysis may again be carried out in two ways. The first requires instrumented animals in which phasic diastolic gradient and volume flow are measured (by an implanted electromagnetic flowmeter). The coefficients for friction, f, and separation losses, s, are then determined by using a computer to find the quadratic equation, $\Delta P = fQ + sQ^2$, which best fits the experimentally recorded flow (Q) and pressure data. The second method can also be carried out in patients or experimental animals by taking orthogonal coronary arteriograms and calculating the coefficients f and s from X-ray geometry as indicated in the flow equation. (There is a third way combining the above two in experimental animals by recording velocity with an implanted periarterial Doppler flowmeter and measuring internal arterial diameters at the Doppler transducer by arteriograms. Volume flow can then be determined as the product of the cross-sectional area at the Doppler transducer times velocity, $A_n \times V$, as shown in the velocity equation and the coefficients f and s determined by either pressure flow data or X-ray geometry.) The closest nonexact approximation of this rule is to measure absolute stenosis diameter in millimeters.

Having begun with a seemingly simple experimental observation, I have followed a tortuous but logical sequence through a minicourse in fluid dynamics. I now return to the original experimental observation.

Mechanisms for Altered Stenosis Severity

Against the problems and background outlined there are four possible mechanisms for altered severity of "fixed" coronary stenoses during changing vasomotor states of the coronary circulation:

1. Vasodilation of the normal coronary artery adjacent to the stenotic segment with more severe percent stenosis, as proposed by Kreuzer and Schenk,[3] or adjacent vasoconstriction with less severe percent stenosis.
2. Further narrowing of the stenotic segment due to a decrease in intraluminal distending pressure after administration of arteriolar vasodilators or expansion of the stenotic segment by increased intraluminal pressure after administration of arteriolar vasoconstrictors, proposed by Logan,[5] Swartz et al.,[6,7] Walinsky et al.[8] and Santamore and Walinsky.[1]
3. Arterial smooth muscle relaxation and vasodilation of the stenotic segment itself after large vessel coronary vasodilations, as proposed by Brown[11] and Doerner[12] and their colleagues.
4. The appearance of fully developed turbulence in the stenotic segment itself (not localized downstream turbulence at the exit end of the stenosis). This not previously proposed possibility can clearly happen at Reynolds numbers found in stenotic segments. At that moment when turbulence develops fully in the stenotic segment, the potential energy (pressure) losses would become so great that normal aortic pressure would be inadequate to maintain flow, which would therefore decrease without change in stenosis geometry. A theoretical analysis of the relation between turbulence, potential energy losses and flow which indirectly bears on this problem has been presented by Berguer and Hwang[20]; however, they did not develop complete equations including viscous losses.

Clinical implications: It is likely that all four mechanisms are acting in various degrees under different physiologic conditions at different levels of stenosis severity. Further studies using high quality quantitative coronary arteriography and high fidelity phasic pressure-flow velocity recordings will be needed to sort out the relative importance of these four possible mechanisms. In any case this discussion illustrates that our previous simple concepts about "impaired plumbing" in coronary artery disease have evolved toward a recognition that the hydraulic characteristics of coronary arterial stenoses are complex biophysical phenomena worthy of serious scientific study. Such studies might also be of therapeutic benefit with further documentation of the radical suggestion by Santamore and Walinsky[1] that, in certain circumstances, selective coronary arteriolar vasconstriction might decrease stenosis severity, increase distal coronary pressure and improve subendocardial perfusion. A combination of selective coronary vasoactive drugs that produced vasodilation of the proximal stenotic arterial segment and distal arteriolar vasoconstriction would appear to merit further investigation by careful quantitative analysis of coronary stenoses and biochemical correlations in animal experiments.

Is the patient drowning in crystalloids?

Deciding whether to treat with crystalloids or colloids a critical decision that is far from easy. Crystalloids an risk edema. Colloids can endanger the patient and eplete the pharmacy budget.

The IL186 WEIL ONCOMETER™ System provides reli- ble colloid osmotic pressure (COP) measurements to elp decide whether crystalloid or colloid fluid therapy called for. Monitoring COP also helps etermine extent of cardiopulmonary ilure, risk of pulmonary edema and emodynamic effects of dialysis.

Consider these IL Oncometer System eatures:

The only system available with mercury manometer for accurate calibration

Quality performance assured via assayed serum albumin

- Fast response time, stat results
- Long-life, easily replaceable membranes
- Flow-through, closed sample chamber
- Small sample size (300 μl)

Let the IL Oncometer System help keep your patient and your pharmacy budget out of troubled waters. For a demonstration or further information, call IL **toll-free: 800 225-4040** (800 342-8856 in MA) Or write for technical papers on COP and its clinical importance.

Liquid K...
It's no picnic.

The tasteless Slow-K tablet that doesn't insult food

Slow-K®

CIBA 165

(potassium chloride) slow-release tablets 8 mEq

The right taste

The right taste in potassium supplementation is no taste or aftertaste. That's the taste of Slow-K. Tasteless. Even when taken with meals, it allows patients to enjoy the flavor of food. Compare this with liquid K's unpleasant taste. It's easy to see why Slow-K was the overwhelming choice of patients in taste comparisons with liquid KCl and potassium gluconate preparations.[1,2]

The right salt

Potassium chloride, the active ingredient of Slow-K, "...is the salt of choice to correct the hypokalaemic alkalosis resulting from thiazides and related diuretics...."[3]

The right delivery

Slow-K delivers KCl slowly, through controlled, gradual release within the gastrointestinal tract. Patients encounter much less nausea, heartburn and diarrhea than with liquid KCl, as demonstrated by comparative studies.[1] (Occurrence of abdominal cramping was comparable.)

Patients also appreciate the convenience of a small, easy-to-carry Slow-K tablet.

Slow-K...When compliance with liquid K supplements is a problem*

*Slow-release potassium chloride tablets should be reserved for patients who cannot tolerate, refuse to take, or have compliance problems with liquid K preparations because of reports of GI ulceration and bleeding with slow-release KCl tablets (total number of GI lesions in both foreign countries and the United States remains less than one per 100,000 patient-years). The incidence of lesions with enteric-coated KCl tablets is 40-50 per 100,000 patient-years.

CIBA

SLOW-K®
(potassium chloride)
slow-release tablets

DESCRIPTION
Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS
BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.

2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.

3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS
In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (eg, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS
Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (eg, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS
Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion, particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram, and clinical status of patient.

ADVERSE REACTIONS
Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE
Usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for prevention of hypokalemia to 40-100 mEq per day or more for treatment of potassium depletion.

Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability insomnia associated with anxiety neuroses and transient situational disturbances; an associated with depressive symptoms and as a treatment of symptoms of anxiety if such s toms are a significant feature of functional or organic disorders, particularly gastrointestir cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by sys atic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucor

Warnings: Not recommended in primary depressive disorders or psychoses. As with all acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, a diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with b turates and alcohol have occurred following abrupt discontinuance of benzodiaze (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). A tion-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveill when on benzodiazepines because of their predisposition to habituation and depende Withdrawal symptoms have also been reported following abrupt discontinuance of ben azepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients: initial daily dosage should not exceed 2mg to avoid sedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may res symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and c sional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that loraze has not been shown of significant benefit in treating gastrointestinal or cardiovascular co nent.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 ye 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum hu therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn v 2 months of first observation. Clinical significance is unknown; but use of lorazepam for longed periods and in geriatric patients requires caution and frequent monitoring for symp of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some hav elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depre effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerg rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of ral Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastrosc malformed skull and microphthalmia) were seen in drug-treated rabbits without relationsh dosage. Although all these anomalies were not present in the concurrent control group, have been reported to occur randomly in historical controls. At 40mg/kg and higher, there evidence of fetal resorption and increased fetal loss in rabbits which was not seen at l doses. Clinical significance of these findings is not known. However, increased risk of con tal malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam meprobamate) during first trimester of pregnancy has been suggested in several stu Because use of these drugs is rarely a matter of urgency, use of lorazepam during this p should almost always be avoided. Possibility that a woman of child-bearing potential ma pregnant at institution of therapy should be considered. Advise patients if they become p nant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of loraze and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like benzodiazepines. As a general rule, nursing should not be undertaken while on a drug many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and gen disappear on continued medication or on decreasing dose. In a sample of about 3,500 an patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6 weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, sea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms function disturbance, various gastrointestinal symptoms and autonomic manifestations. dence of sedation and unsteadiness increased with age. Small decreases in blood pres have been noted but are not clinically significant, probably being related to relief of anxiety

Overdosage: In management of overdosage with any drug, bear in mind that multiple ag may have been taken. Manifestations of overdosage include somnolence, confusion and c Induce vomiting and/or undertake gastric lavage followed by general supportive care, mor ing of vital signs and close observation. Hypotension, though unlikely, usually may be contr with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined

Ativan® IV for (lorazepam) Anxiety

***Dosage:* Individualize for maximum beneficial effects. Increase d gradually when needed, giving higher evening dose before increas daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dos may vary from 1 to 10mg/day in divided doses. For elderly or de tated, initially 1-2mg/day; insomnia due to anxiety or transient sit tional stress, 2-4mg h.s.**

***How Supplied:* 0.5, 1.0 and 2.0mg tablets.**

The anxious heart.

Since anxiety so often accompanies cardiovascular disease, you may wish to institute adjunctive therapy to help bring this complicating factor under control.

Seven benzodiazepines are now at your disposal. All of them are anxiolytics. One of them—Ativan (lorazepam)—has been specifically evaluated in seven double-blind, controlled studies involving 423 patients (211 on Ativan) and found significantly effective in the relief of anxiety associated with organic and functional cardiovascular disorders. The cardiovascular component has not, of course, been shown to be significantly benefited by such therapy.

In addition to this outstanding record of clinical usefulness, Ativan offers you a unique pharmacokinetic profile. Unlike older benzodiazepines, it does not generate multiple active metabolites; steady-state serum levels are rapidly achieved and disappear rapidly once you decide to discontinue therapy. (The pharmacokinetic profile of a drug can define such characteristics as absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Compatible with cardiotonics, antihypertensives, diuretics, anticoagulants and nonnarcotic analgesics*...usually well tolerated...simple to use on a b.i.d. schedule...a preferred prescription to control anxiety in cardiovascular disease.
